Abstract

Modeling, evidence

Null hypothesis significance testing is frequently cited as a threat to the validity and 18 reproducibility of the social sciences. While many individuals suggest we should focus on 19 altering the p-value at which we deem an effect significant, we believe this suggestion is 20 short-sighted. Alternative procedures (i.e., Bayesian analyses and Observation Oriented 21 Modeling; OOM) can be more powerful and meaningful to our discipline. However, these 22 methodologies are less frequently utilized and are rarely discussed in combination with 23 NHST. Herein, we discuss the historical roots, procedures, and assumptions of three 24 methodologies (NHST, Bayesian Model comparison, and OOM), then compare the possible 25 interpretations of three analyses (ANOVA, Bayes Factor, and an Ordinal Pattern Analysis) in various data environments using a simulation study. The simulation generated 20,000 unique datasets which varied sample size (Ns of 10, 30, 100, 500, 1,000), and effect sizes (ds of 0.10, 0.20, 0.50, 0.80). Through this simulation, we find that changing the threshold at which p-values are considered significant has little to no effect on conclusions. Further, we find that evaluating multiple estimates as evidence of an effect can allow for a more robust and nuanced report of findings. These findings suggest the need to redefine evidentiary value 32 and reporting practices. 33 Keywords: null hypothesis testing, p-values, Bayes Factors, Observation Oriented 34

Beyond p-values: Utilizing Multiple Methods to Evaluate Evidence

36

Recent events in psychological science have prompted concerns within the discipline 37 regarding research practices and ultimately the validity and reproducibility of published 38 reports (Etz & Vandekerckhove, 2016; Lindsay, 2015; Open Science Collaboration, 2015; van 39 Elk et al., 2015). One often discussed matter is over-reliance, abuse, and potential hacking of p-values produced by frequentist null hypothesis significance testing (NHST), as well 41 misinterpretations of NHST results (Gigerenzer, 2004; Ioannidis, 2005; Simmons, Nelson, & Simonsohn, 2011). We agree with these concerns and believe that many before us have voiced sound, generally accepted opinions on potential remedies, such as an increased focus on effect sizes (Cumming, 2008; Lakens, 2013; Maxwell, Lau, & Howard, 2015; Nosek, Spies, & Motyl, 2012). However, other suggestions have been met with less enthusiasm, including a recent article by Benjamin et al. (2017) advocating that researchers should begin thinking only of p-values less than .005 as "statistically significant", thus changing  $\alpha$  levels to control Type I error rates. Additionally, Pericchi and Pereira (2016) promote the use of fluctuating  $\alpha$  levels as a function of sample size to assist with these errors. We argue it is not the p-value that needs to be rethought when seeking evidence, but rather what that p-value can tell you in relation to other indicators. While NHST and p-values may have merit, 52 researchers have a wealth of other statistical tools available to them. We believe that 53 improvements may be made to the sciences as a whole when individuals become aware of the tools available to them and how these methods may be used in combination to strengthen 55 understanding and conclusions. These sentiments have been shared by the American 56 Statistical Association who recently held a conference focusing on going beyond NHST, 57 expanding their previous stance on p-values (Wasserstein & Lazar, 2016). 58 Therefore, we undertook this project to begin to let researchers see the similarities and differences both within the methodological design, as well as within the interpretations of statistics as meaningful. Herein, we have chosen three methodologies to focus on: NHST, 61 Bayes Factor comparisons, and Observation Oriented Modeling. These three approaches will

be compared via simulated data using a repeated measures design with a Likert-type scale as the outcome variable. The aims of this study will be to discuss the conclusions that these three methods would make given the same data, and to compare how often these methodologies agree within different data environments (i.e. given different sample sizes and effect sizes). We hope that by discussing these methodologies in terms of a simple statistical analysis researchers will be able to easily compare and contrast methodologies. For this discussion, it is important to understand their historical background, procedural steps, and limitations, which are outlined below. After this discussion, we describe a simulation study comparing methodologies and  $\alpha$  criteria, and end with a potential implications for researchers.

# **Null Hypothesis Significance Testing**

# 74 History

73

88

Many attribute the frequentist NHST procedure to Ronald A. Fisher (Fisher, 1932). 75 However, Fisher's ideas are a far cry from the NHST procedure implemented today. Fisher 76 believed in creating one "null" hypothesis, which he described as a hypothesis to be 77 "nullified", or shown incorrect, not as a zero-difference hypothesis (Lehmann, 2011). He also believed that the use of any omnibus level of significance showed a "lack of statistical thinking" (Gigerenzer, Krauss, & Vitouch, 2004). He instead believed we should report the exact significance value of a test and let others make their own decision about the claims, 81 which is more in line with the typical reporting recommendations provided by the American Psychological Association (American Psychological Association, 2010). Fisher spoke of this work to William Gosset, the man who created the Student's t-test and contributed work on the correlation coefficient (Lehmann, 2011). Gosset in turn discussed the idea of an alternative hypothesis, a piece not included in Fisher's procedure, with decision theorist Egon Pearson.

From this discussion, Egon Pearson and Jerzy Neyman created Neyman-Pearson

decision theory. This theory consists of two hypotheses (i.e., null and alternative) and a binary decision criteria (i.e., significant or not, Lehmann, 1993). However, this procedure created the possibility of researcher decision errors (Dienes, 2008). A researcher may falsely 91 reject the null hypothesis (Type I error,  $\alpha$ ) or falsely fail to reject the null (Type II error,  $\beta$ ). 92  $\alpha$  levels set the binary decision criteria, which are used as the critical p-value for hypothesis 93 testing (i.e., p < .05), and are thus seen as evidence to reject the null hypothesis.  $\beta$  and power are inherently linked, as the likelihood of finding a true effect increases when beta 95 decreases (Maxwell & Delaney, 2004). Although  $\alpha$  values can be chosen to be quite small, and methods can decrease  $\beta$  values as well, a researcher can never know if they have made 97 the correct decision, or a decision error. Thus, Neyman and Pearson clearly state that a hypothesis should not be blindly supported based solely on the estimates of one statistical test, and that replication and reproduction of results are imperative. The recent work of the Open Science Collaboration (2015) has also highlighted the need for replication studies and 101 interpretation of results in an appropriate context. Additionally, Neyman and Pearson 102 emphasized that use of set  $\alpha$ s and  $\beta$ s is illogical and sought instead for researchers to adjust 103 their analysis to the needs of the particular task at hand (Gigerenzer, 2004). 104

#### 105 Typical NHST Procedure

111

112

Neither Fisher's hypothesis testing, nor Neyman-Pearson decision theory quite match
the NSHT procedure as it is taught and applied today. Psychologists have largely adopted
an amalgamation of the two approaches. Here, we attempt to outline what we believe is the
most appropriate way to carry out the traditional NHST procedure, although we note that
this set of steps is not necessarily how researchers carry out the procedure in practice:

1) Create two hypotheses, one to be "nullified" and one "alternative" hypothesis. These can be operationalized in our example data as follows:

$$H_0: \mu_1 = \mu_2 = \mu_3$$

$$H_A: \mu_1 \neq \mu_2 \neq \mu_3$$

- Select an  $\alpha$  level that is appropriate given the context of your research, your analysis plan, and your research question, and do not blindly adopt an omnibus critical p-value.
- Compute your given analysis and identify the corresponding p-value. If your p-value is less than the chosen  $\alpha$ , reject the null hypothesis and state that there appear to be differences between your means; however, if your p-value is greater than or equal to the value selected, do not reject the null hypothesis, and state that a difference between the means could not be supported.

While the NHST procedure itself gives us testable models, the specific analysis used to 120 test these models here—the repeated measures ANOVA with 3 levels—requires some 121 additional assumptions that must be met before an analysis is begun (Tabachnick & Fidell, 122 2012). Data need to have no missing values and no outlying or influential observations. Data 123 must have a normal sampling distribution, be linearly related, and have independent errors. 124 Depending on the statistical test, data must also be checked for equal variances, sphericity, 125 and additivity. These assumptions can be checked and, if necessary, corrected for; however, 126 violations of these assumptions can lead to inaccurate decisions and attenuated power. 127

While this approach is widely used, there are many limitations associated with it. 128 First, this method can be sensitive to violations of the stated assumptions if the sample size 129 is not large enough to create a normal sampling distribution. Additionally, phenomena that 130 are not linearly related or data that violate any of the other assumptions mentioned above can lead to inappropriate decisions (Tabachnick & Fidell, 2012). Even if assumptions are 132 met, or nonparametric tests are implemented, this methodology does not allow a researcher 133 to state anything about the absence of an effect (i.e., no true differences). Through 134 traditional NHST, one can only discuss evidence regarding the alternative hypothesis; one 135 can never support the null hypothesis through this procedure. Given the recent findings 136

regarding reproducibility, showing support for the absence of an effect is even more crucial (Bakker, van Dijk, & Wicherts, 2012; Lakens, 2017).

### **Bayes Factors**

#### 140 History

139

Thomas Bayes was a statistician and Presbyterian minister whose works are still 141 influential today (Bellhouse, 2004). Bayes' theorem solved the inverse probability problem, namely that through the frequentist approach, one can only know the probability of data 143 existing given a hypothesis being true, never the probability of a hypothesis being true given that the data exist (Dienes, 2008). Bayes' theorem allows one to calculate the probability of a hypothesis given some data (posterior belief) by using how probable one believes the 146 hypothesis to be before data was collected (prior belief) and how probable one believes the data to be given one's hypothesis (likelihood). Thus, with his theorem, researchers are able 148 to update (through the use of the likelihood) our initial beliefs (our prior) given some data 149 (Gelman, 2004). Pierre-Simon Laplace pioneered Bayesianism and advocated for a broader 150 interpretation of this theorem (De Laplace, 1774). The use of Bayesian statistics has been 151 suggested as an NHST alternative (Dienes, 2014; Wagenmakers, 2007), but this approach has 152 largely been undervalued in favor of frequentist methods as, until recently, Bayesian analysis 153 required considerable computational effort. However, today we possess the technology 154 necessary to conduct Bayesian analyses efficiently. While open source software, such as R155 and JASP, require minimal learning to be able to effectively operated (Morey & Rouder, 156 2015), researchers will need to invest more effort to understanding the focus and 157 interpretation of Bayes Factor comparisons as they differ from traditional NHST. 158 The Bayesian framework can be viewed as a continuum, with objective Bayesian 159 analyses on one end, and subjective Bayesian analyses on the other (Press, 2002). While this 160 topic could lend itself to its own manuscript, here we will simply summarize the two 161 endpoints, and discuss where our analysis may be perceived to fall on the line. Objective 162

Bayesian analysis is closest to frequentist theory, as priors are set to be as uninformative as 163 possible to allow little, if any, influence on the estimates and distribution of the posterior; 164 thus, the data is allowed to maximally effect the posterior distribution. On the other end, 165 subjective Bayes analyses include rigorously informed priors so that current knowledge can 166 play a large role in the posterior. Our current analysis splits these two; we do not utilize 167 completely uniformed (objective) priors, as we can adjust for basic knowledge of the 168 constraints of our data type. Given the usual lack of information about underlying 169 distributions, a wider band of inclusion was used for prior information. The BayesFactor 170 package (Morey & Rouder, 2015) assists greatly in the choice of prior and is especially 171 user-friendly for applied researchers, as it makes use of recommended default priors that have 172 been chosen to be safe to assume under a broad range of data and topics (Rouder, Morey, 173 Speckman, & Province, 2012; Rouder, Speckman, Sun, Morey, & Iverson, 2009). Instead of conventional F, t, and p-values, a ratio of the likelihood of the alternative model to the null 175 is report, usually  $BF_{10}$ . For instance,  $BF_{10} = 20$  would indicate that the effects model is 176 favored 20 to 1 over the null model. Conversely, if the  $BF_{10}$  were 0.10, the null model is 177 favored 10 to 1 over the effects model. 178

#### 179 Typical Procedure

180

The procedure behind Bayes Factor (BF) comparisons requires two steps.

1) One must design two models for the data. For our purposes, the first of these models 181 will be the null model, which states that there are no differences between means. The 182 second model for these analyses is the effects model, which states that each mean is 183 allowed to be different from the grand mean. In designing these models, one must 184 choose the prior distributions that are believed to describe the data. Reasonable 185 expectancies of where the data lie should be incorporated in this decision based on 186 previous research into the studied phenomena (Rouder et al., 2012). These can be 187 operationalized as follows: 188

190

191

192

193

$$H_0: X_{ij} \sim N(\mu, \sigma^2)$$

$$H_A: X_{ij} \sim N(\mu + \alpha_i, \sigma^2)$$

2) Analyze the data given the selected priors and models. Consider the BF and use the  $BF_{10}$  as evidence of how one should update their beliefs about the models.

Based on the flexibility of the analysis, the only assumption that needs to be made is that data exists such that two competing, plausible models with different constraints may be specified.

Bayesian inference improves upon the traditional frequentist point of view by allowing 194 not only a clear interpretation of the evidence provided by the data, but also the ability to 195 speak in favor of the null hypothesis. It is important to note that while previous work has 196 indicated that p-values and BF largely agree on which hypothesis should be supported, they 197 differ in the strength of that conclusion, especially when p-values were slightly lower than  $\alpha$ 198 (i.e., .05 to .01; Wetzels et al., 2011). However, some limitations do arise in this paradigm. 199 Bayesian analyses require the researcher to take an active role in the choice of prior 200 distributions for the phenomenon they are modeling, and this decision can take some effort 201 to fully understand; however, in the meantime, there are packages such as BayesFactor that 202 allow the researcher simple default options that can readily lend themselves to many research 203 areas with little fear of being outrageous specifications. Further, unlike NHST, Bayesian 204 analyses do not necessarily control long-run error rates, as the focus is on updating current 205 model beliefs. Another concern that many researchers have is that these analyses are 206 necessarily sensitive to prior choice. However, research has shown that the choice of priors has essentially no effect on conclusions when sufficient data has been collected as the priors 208 give way to the weight of the data (Klugkist & Hoijtink, 2007; Rouder et al., 2012) and when 209 reasonable priors are considered, data are only mildly sensitive to these (Haaf & Rouder, 210 2017). Finally, many believe Bayesian analysis to be too computationally intensive to 211 complete. However, many simple programs, packages, and tutorials exist to help ease the 212

transition from frequentist to Bayesian analysis (JASP Team, 2017; Kruschke, 2014; Morey & Rouder, 2015).

## **Observation Oriented Modeling**

# 216 History

215

James Grice argues that our problems as a science go beyond use of NHST and extend 217 into the philosophical ideas underpinning our research. Therefore, he developed a new 218 paradigm called Observation Oriented Modeling (OOM, Grice, 2011, 2014; Grice, Barrett, 219 Schlimgen, & Abramson, 2012). He reasons that by viewing psychology through the lens of realism, instead of positivism, we should be able to properly and effectively conduct research and analyze data. In contrast to positivism (i.e., which is solely concerned with finding an effect, not with how the effect occurred), realism is the belief that effects conform to their cause and that given the correct models of these processes we can begin to understand our 224 reality. By viewing science as knowing nature through its causes, we can use Aristotle's four 225 causes (material, efficient, formal, and final) to think in terms of structures and processes in 226 order to explain phenomena. Switching to this philosophy allows for techniques that match 227 the daily activities of social scientists in their endeavors to unravel the story of how humans 228 operate. Using OOM, a researcher does not focus on population parameters and the various 220 assumptions underlying statistical tests (e.g., random sampling, normality, homogeneity of 230 population treatment differences, etc.). Instead, the researcher alternatively focuses on 231 observations at the level of the individual. 232

Generally speaking, this approach can handle any type of data, including ordinal rankings and frequency counts, as all analyses are calculated in the same general fashion (see Valentine & Buchanan, 2013 for an example). This simplicity occurs because OOM works on the deep structure of the data. Through observational definition, the program separates these units into binary code. Deep structures can be arranged to form a matrix, which can then be manipulated via matrix algebra, binary Procrustes rotation, and other operations to

investigate the data. The most important values from any OOM analysis are the PCC (percent correct classification) values. These values represent the summation of how well an 240 individual's responses matched the stated or expected pattern or, in the case of causal 241 modeling, how many of the individual's conformed to a given cause. Complete matches are 242 the proportion of observations that match the researcher-designated pattern on all 243 dimensions. For example, in a three-level Ordinal Pattern Analysis (OPA), a person would 244 be tallied as a "complete match" if the ordinal pattern of his/her data matched the expected 245 ordinal pattern across all three levels. Imagine we have set a pattern that designates that time 1 responses should be less than time 2 which should be less than time 3. Given the data 247 for two hypothetical individuals in Table 1, we can see that person A matched the pattern 248 completely, and therefore would be counted in the PCC value. However, while person B 249 matched the first part of our pattern (time 1 less than time 2), they did not match on the third point of our pattern (time 2 less than time 3); thus, they would not be counted in the 251 PCC value. The PCC value replaces all of the conventional values for effect size used in statistical analyses. The analysis we focus on here (OPA) does not form any type of linear or 253 nonlinear equation or regression, but simply looks for those individuals who match the 254 expected ordinal pattern (Grice, Craig, & Abramson, 2015). The main point of the analysis, 255 then, is to see how many people fit the expected pattern which is based on a causal theory. 256 If all causes are accounted for in the study and observations have been made with sufficient 257 precision and accuracy, then 100% of the persons should fit the expected pattern; otherwise, 258 a lower PCC value will be expected and it is up to the researcher to determine how high a 259 PCC must be in order to support an inference to the causal mechanism. 260

In OOM, p-values are no longer utilized (Grice, 2011). As a secondary form of reference value, a chance value (c-value) is obtained, which is a type of randomization test in which the researcher determines the number of randomized trials for the test (e.g. 1,000 or 5,000 randomized versions of actual observations). This procedure is akin to permutation tests, where the original data is shuffled a number of times to create comparable data sets.

These randomized data sets are then compared to the designated pattern. If the randomized data sets fit the pattern as well as or better than the actual data does, the c-value will be high (close to 1). Low c-values (close to 0) indicate a pattern of observations that is improbable (i.e., unlikely produced by chance) when compared to randomized versions of the same data. Although low c-values, like low p-values, are desirable, c-values do not adhere to a strict cut-off and should be considered a secondary form of confirmation for the researcher that their results are distinct.

# 273 Typical Procedure

274

275

276

277

278

279

280

281

The OPA is analogous to repeated measures ANOVA and contains two steps.

1) Designate the expected ranked pattern: each variable as being higher, lower, or equal to the other variables. For instance, for our analyses we defined the following pattern of individual responses:

$$X_{i_1} < X_{i_2} < X_{i_3}$$

2) Analyze the data using the OPA. Consider the PCC and c-values in light of the data and use your best judgment as to whether or not the data conform to the expected pattern. This analysis only requires the assumption that the data exists such that a pattern may be designed.

As with all of these methodologies, limitations do exist. This approach is largely
concerned with patterns of responses, not with magnitudes of differences, which may be an
integral piece of information to some researchers. Unlike all approaches mentioned before, we
do not discuss the probability of some data given our hypothesis here, and instead focus on
the observed responses of the individual and how it may or may not behave as expected.
Finally, similar to the Bayesian analysis, long-run error rates are not discussed in this
methodology.

# A Simulation Study

#### Simulated Data

289

314

315

In this study, we generated 20,000 datasets by manipulating sample size and effect size 291 for a repeated measures design with three levels. A repeated measures design was chosen as 292 it is widely used across many disciplines of psychology. These datasets were created using 293 the mvtnorm package in R (Genz et al., 2017), and all code for simulations can be found at https://osf.io/u9hf4/. Interested readers can easily adapt the R code to incorporate different 295 research designs. Likert data, ranging from 1 to 7, was created by rounding mytnorm 296 estimates to whole numbers and truncating any data points out the appropriate range 297 (i.e. values < 1 were rounded to 1, and values > 7 were rounded to 7). We specifically chose 298 Likert-type data as this data type is one of the most common data types utilized by most 299 social scientists. Additionally we add to the literature as other simulations have chosen to 300 use completely continuous data (i.e., simulated numbers are often precise to 10+ decimals, 301 which is unlikely for normal samples). The population means for each level were set to 2.5, 302 3.0, and 3.5, and effect sizes were manipulated by adjusting the standard deviation to create 303 negligible effects (SD = 3.39, d = 0.10), small effects (SD = 3.00, d = 0.20), medium effects 304 (SD = 0.50, d = 0.50), and large effects (SD = 0.10, d = 0.80) using Cohen (1992)'s 305 traditional guidelines for d interpretation. The smallest effect size was set such that Likert 306 style data could still be retained with the smallest possible effect size. Sample size was 307 manipulated at 10, 30, 100, 500, and 1,000 data points. All combinations of the five sample 308 sizes and four effect sizes were created, and each dataset was simulated 1,000 times, totaling 309 20,000 datasets. 310 The advantage of using mvtnorm and set SDs for each group was the ability to 311 approximate the assumptions of normality by randomly generating from a multivariate 312 normal distribution, and homogeneity by setting equal SDs for each group. In a repeated 313

measures design, the assumption of sphericity was met by setting the correlations between

levels in mvtnorm to zero. By maintaining the lowest level of relationship between levels, we

additionally controlled for power and examined situations of significance given the lowest power scenario. During the data simulation, the standard deviation of the difference scores was examined to maintain differences greater than zero, especially for low n simulations.

# 319 Analyses Performed

Descriptive Statistics. Means, mean differences between levels, and the confidence intervals for each mean can be found in the complete dataset online, https://osf.io/u9hf4/. For each simulation, we also calculated d values using the standard deviation of the difference score as the denominator ( $d_z$ , Lakens, 2013). The MOTE library was used to calculate the non-central confidence interval for each d value as well (Buchanan, Valentine, & Scofield, 2017; Cumming, 2014). This data was mainly used to determine if simulations were meeting expected values overall.

Parametric NHST - Repeated Measures ANOVA. Repeated measures
ANOVA using the ezANOVA() function in the ez library was utilized with type three sum of
squares (Lawrence, 2017). This style of ANOVA is used to compare the same individuals
across multiple or all conditions in an experiment. The null hypothesis states that there are
no significant differences between population means, and the research hypothesis posts that
there are differences between population means, but does not specify which population
means may differ, just that one or more will differ as the alternative. This test uses the Fdistribution focusing on p values.

To determine where differences may exist, post hoc dependent t-tests are normally analyzed in the event of a significant F-ratio. We did not run all pairwise comparisons, instead focusing on the linear trend simulated by comparing level one to two and level two to three. This set of comparisons also controlled the effect size between comparisons, as comparing level one to three would have doubled the effect size. However, we assumed that the typical researchers might compare all three pairwise combinations in practice and used a Bonferroni correction across all three possible pairwise combinations to calculate p values for

post hoc tests. Therefore, while we only discuss the two comparisons, we utilized the more 342 stringent cutoff of the Bonferroni correction as we believe this procedure would be how the 343 majority of researchers would handle the data. Interested readers can find all three 344 comparison values in the complete dataset online. A p-value of less than .05 was binned as 345 significant, whereas p-values ranging from .10 to .05 were binned as marginally significant. 346 Any p-values larger than .10 were binned as non-significant. A second set of p-value 347 comparisons was calculated given Benjamin et al. (2017)'s suggestion to change  $\alpha$  criterion 348 to less than .005. Any p-value less than .005 was binned as significant, while data ranging from .005 to .10 was marginal or suggestive, and p > .10 was non-significant. 350

Bayesian Analysis: Bayes Factor. We compared a null model with one grand 351 mean for all three levels to an effects model wherein means were allowed to differ using the 352 BayesFactor package (Morey & Rouder, 2015). The default in this package is a Jeffreys prior 353 with a fixed rscale (0.5) and random rscale (1.0). BF were calculated, and follow up t-test 354 BFs were computed for the same two comparisons as in the previous models using default 355 priors from the BayesFactor package (e.g., Jeffreys prior for population variance, Cauchy 356 prior for standardized effect size). To compare Bayesian results to other statistical methods, 357 we used recommendations from Kass and Raftery (1995) to bin results into weak evidence (BFs < 3), positive evidence (e.g., akin to marginal p-values, BFs = 3-20), and strong 359 evidence (BFs > 20). BF interpretation should focus on understanding the odds of model 360 ratios, and these bins are used here as a convenient comparison to procedures that do have 361 set criteria for interpretation (Morey, 2015). 362

OOM: Ordinal Pattern Analysis. An R script of the Ordinal Pattern Analysis
from Grice et al. (2015)'s OOM program was provided from Sauer and Luebke (2016). We
set the expected ranked pattern as level one less than level two less than level three. Once
this pattern is defined, we then analyzed the data to see if each individual's set of
observations matched this expected ordinal pattern. PCC values were generated, and
c-values were computed by randomizing the data 1,000 times. Solely for purposes of

comparison, we used the following significance coding schema: significant studies had a high PCC value (.50 < PCC < 1.00) and a low c-value (c < .05), marginal studies had a high PCC value and a moderate c-value (.05 < c < .10), and non-significant studies had low PCC values (PCC < .50), regardless of their c-values.

Results

### Percent of Estimates

For all simulations, we first binned the estimates into significant, marginal, and 375 non-significant effect categories as described in the Analyses Performed section above. Next, 376 we calculated the percentage of these analyses that would be classified into each of these 377 categories, separated about by statistical analysis, sample size, and effect size. These 378 estimates were binned across both the overall and follow up post hoc tests, and the combined 379 data is presented for this analysis. Since all three categories of binning total to 100%, we 380 present only the significant and non-significant results. All analyses and findings can be 381 found online at https://osf.io/u9hf4/. 382 Significant critical omnibus estimates are presented in Figure 1. This, as well as all 383 figures discussed in this manuscript may be viewed as interactive graphics on our webpage at 384 http://96.242.30.151:3838/althhst/. All of these graphics are interactive and can be 385 manipulated for more precise viewing. 386 For negligible effects at p < .05 (solid lines), we found that NSHT analyses showed a

For negligible effects at p < .05 (solid lines), we found that NSHT analyses showed a predictable Type I error bias, in that they detected significant estimates with extremely small d values as sample size increased. Binned BF values showed a similar pattern, but were more conservative with less percent significant estimates. OOM analyses were the most conservative, essentially never detecting an estimate in the negligible effect simulations. Small effect sizes showed the same pattern for NHST, BF, and OOM results, with the proportion of significant estimates increasing more rapidly and asymptoting at a smaller sample size than negligible effects. At medium effect sizes, NHST analyses nearly always

detected significant estimates, while BF and OOM analyses would have been considered 395 "significant" around 75% of the time. Interestingly, with large effect sizes, OOM analyses 396 mirrored NHST by always detecting estimates, and BF analyses were generally more 397 conservative except at the largest sample size. Figure 1's dashed lines indicate the results if 398 values were binned at p < .005, and the differences between these results were very subtle. 390 Lowering  $\alpha$  reduced the number of significant estimates at small n values for all four effect 400 sizes, with more pronounced differences at negligible and small effect sizes. However, the 401 graphs converged to the same conclusion that large enough sample sizes could produce 402 significant results at negligible and small effect sizes. 403 Figure 2 portrays the results for non-significant binned simulations, which were the 404 same for both  $\alpha$  criterion. Across all effect sizes, BF and NHST showed similar results, 405 where non-significant estimates were detected at lower sample sizes for negligible and small 406 effect size simulations. At medium and large effect sizes, almost all estimates would have 407

around zero. OOM displayed a conservative set of findings, showing nearly 100%

non-significant estimates at negligible and small effect sizes (mirroring results from Figure 1).

been considered significant, therefore, detection rates for non-significant estimates were

411 At medium effect sizes, approximately a quarter of estimates were non-significant,

illustrating the conservative nature of OOM interpretations.

#### 413 Percent Agreement

408

A goal of this project was to expand the toolbox of options for researchers to determine
what evidence supports their hypotheses by examining multiple methodologies. We
calculated the percent of time that all analyses agreed across overall and post hoc comparison
estimates. Figure 3 illustrates the pattern of 100% agreement on effects for critical omnibus
tests only at each sample size and effect size. Figure 4 portrays the results for post hoc tests,
which only uses NHST and Bayes Factor analyses, as OOM does not have a post hoc test
in the test is a pattern analysis that presupposes the expected direction of post hoc tests).

When effect sizes were negligible and for small effects, agreement was best across small 421 samples and decreased across sample size, as NHST was overly biased to report significant 422 estimates and OOM and BF were less likely to do so. For medium and large effect sizes, 423 50-75% agreement was found, usually regardless of sample size. Additionally, we found that 424 for negligible, small, and medium effects, agreement for post hoc tests was higher than 425 agreement for overall comparisons. The post hoc comparisons for levels 1 to 2 and levels 2 to 426 3 were less likely to be binned as significant across negligible and small effects, so the 427 agreement levels were higher for these individual comparisons due to non-significant follow 428 up tests. The critical omnibus test was more likely to be significant due to the inclusion of 429 effect of comparisons between level 1 and 3, which were double the effect size. However, 430 these post hoc comparisons do not include the conservative significant binning from OOM, 431 which decreased critical omnibus 100% agreement seen in Figure 3. Again, the differences 432 between p < .05 and p < .005 were minimal. Complete tables of percentages of binning 433 across critical omnibus and post hoc tests, along with agreement percentages broken down by bins can be found at https://osf.io/u9hf4/. 435

#### 436 Criterion Comparison

As the relationship between BF and p-values is already well documented, we will not discuss them here beyond stating that we found the expected pattern shown in previous work (Rouder et al., 2012), and that individuals who wish to view this comparison, as well as all the other comparisons discussed here should visit our interactive Shiny application at https://osf.io/u9hf4/. Of interest was the comparison of OOM indices to traditional NHST and Bayesian indices. First, in Figure 5, PCC values are plotted against log BF values and p-values. The log of BF was taken to include all values on a viewable axis, and all infinity values were windsorized to the next highest point. Increasing sample size is shown by increasing point size and lighter colors. Additionally, since OOM values are a combination of PCC and c-values, c-values below .05 are shown as Xs instead of dots. Therefore, all values

PCC >= .50 that are also denoted as Xs would be considered significant in this example.

The provided Shiny application uses color to distinguish sample size differences, as well as

includes options to create each combination effect size and criterion individually. Only two

graphs are provided here to save space.

In Figure 5, the left hand column portrays the relationship between log BF values and 451 PCC values in negligible and medium effect sizes. With negligible effect sizes, we found large 452 variability in PCC values across a small span of BF values while sample sizes remained low, 453 but as N increased, we saw that the range of PCC values narrowed considerably with 454 increasing BF values. Therefore, as sample size increased, the PCC values constricted, while 455 BF values expanded. A similar pattern appeared when viewing the medium sample size 456 graph, as again PCC values became less variable with increased sample size, and BF tended 457 to increase both in variability and in value as the sample size grew. Here, we can see a 458 benefit of PCC, along with c-values, as increasing sample size portrayed more precision in 459 PCC, instead of the increased variability found in BF.

It is also important to note that within the negligible effects graph, while many of
these PCC values reached high values, that these values did not denote patterns that would
necessarily be seen as unique. c-values were a secondary measure of evaluation that
eliminated a number of these matches from being considered meaningful. A large majority of
points with larger sample sizes on the figure included low chance values, however, the PCC
values for these simulations were lower than a meaningful percent used for cutoff criterion.
This two-step process helped to weed out effects that were negligible, especially at larger
sample sizes.

Additionally, we compared p-values and PCC values, which are illustrated on the right hand side of Figure 5. Again, PCC values showed far more variability with small sample sizes, and the p-values associated with these smaller sample sizes were also quite variable.

Importantly, even when an effect was negligible, PCC values become less variable and also indicated that there was little evidence of the pattern at hand by shifting toward zero.

p-values lost almost all of their variability at high sample sizes and decreased to minuscule 474 values, thus, pointing toward rejecting the null hypothesis. With medium effect sizes, both 475 p-values and PCC values were variable at small sample sizes. At larger sample sizes, p-values 476 decreased towards floor effects (i.e. closer to zero), while PCC values simply narrowed in 477 range shifting slight above .50. The benefit of multiple criterion evaluation here is clear, as 478 p-values indicated significance as sample size increased, while PCC values present a more 479 stable picture of effect sizes. While multiple criterion may not completely reduce false 480 positives in the literature, the relationship between these values illustrates that multiple 481 indices can provided a clearer picture of the evidentiary value available in a study. # 482 Limitations 483

Within any study a number of limitations exist. The largest limitation of our study is 484 that we chose to focus on a simple three level repeated measures ANOVA design. The 485 benefit to this focus is the simplicity of understanding the relationship between these values, 486 while also using a well understood NHST procedure. However, is possible that these same 487 relationships may or may not exist in alternative design contexts. Additionally, our choices 488 for classification of "significant" effects for p-values, Bayesian factors, PCC, and c-values was 480 based on what we believe a reasonable researcher may designate; however, these 490 classifications may vary in the real world. We provide open access to our simulations and 491 code so that an interested party can tinker with these choices. We believe the global 492 conclusions would likely be similiar across changes, however, the specific percentages and 493 patterns would likely differ. Finally, due to the specification of our simulation we did not violate any statistical assumptions. It is possible—and highly likely—that violation of these assumptions may cause changes in the relationships we see here.

497 Discussion

This manuscript was designed to showcase available methodologies to researchers and to compare the conclusions each methodology might make in a given data environment. We

believe that the application of multiple methodologies might assist in strengthening our 500 conclusions and improving reproducibility by giving researchers the ability to weight various 501 forms of evidence. We found that changing the threshold at which p-values are deemed 502 "significant" had little to no effect on conclusions, especially at large sample sizes, regardless 503 of effect size. This finding is notable as the article by Benjamin et al. (2017) states that an 504 increase in sample size is likely to decrease false positives "by factors greater than two" 505 (p. 10), and work by Pericchi and Pereira (2016) state that an adaptive level of significance 506 would be beneficial in these circumstances, neither of which are not supported by our 507 simulations. Our science will not grow by moving the significance line in the sand, as this line 508 has already been shown to have "no ontological basis" (Rosnow & Rosenthal, 1989, p. 1277). 509 Instead, we need to embrace the multitude of perspectives available to us and to begin to use 510 a combination of approaches to qualify the strength of evidence. By comparing multiple methodologies, we can see a more nuanced version of our data. Additionally, while all of 512 these methods have limitations, when taken together these methods can begin to overcome 513 these limitations. For instance, given a large sample size, we would expect that BF values to 514 be very large and p-values to be very small—both indicating that an effect exists. However, 515 if we also have a PCC value of .4, we may see that it is possible that this effect is very small, 516 and possibly negligible. This may help to curb our enthusiasm over small or negligible effects 517 that may possibly not replicate. Regardless if analyses agree or disagree on the presence of 518 an effect, a researcher can investigate the size of the effect and discuss conclusions 519 accordingly. Each methodology behaves slightly differently in given data environments, 520 which might begin to highlight meaningful differences when discussed together. 521

Some may contest that all of these analyses are capable of being hacked, like p-values, through researcher degrees of freedom, choice of priors, or pattern choice, among other actions (Simmons et al., 2011). Transparency throughout the research process is key to eliminating these issues, as  $\alpha$  changes may only encourage bad research practices with the current incentive structure on publishing. Although we have the capability to share research

across the world, research often still occurs behind closed doors. The Open Science
Framework grants insight into research processes, allowing researchers to share their
methodologies, code, design, and other important components of their projects. In addition
to posting materials for projects, pre-registration of hypotheses and methodology will be an
important facet in scientific accountability. Further, with increased transparency editors and
other researchers can weigh the evidence presented according to their own beliefs.

Our key suggestion in this project is the redefinition of evidentiary value. The current 533 focus on p-values has shown to be problematic, as many of the studies from the Open 534 Science Collaboration (2015) do not replicate at p < .05 or p < .005 (Lakens et al., 2017). 535 With the change in transparency mentioned above, publishing research with solid research 536 designs and statistics, regardless of p-values, will allow for a broader range of evidence to 537 become available. Publishing null findings is critical in replication and extension for 538 discovering the limits and settings necessary for phenomena. Registered replications and 539 reports will allow studies to be accepted prior to results being known, thus allowing 540 researchers to focus on experimental design and hypotheses appriori instead of p-values post 541 hoc. Reports should describe multiple indicators of evidence, such as effect sizes, confidence 542 intervals, power analyses, Bayes Factors, and other descriptive statistics (Finkel, Eastwick, & Reis, 2015; Nosek & Lakens, 2014; Van't Veer & Giner-Sorolla, 2016).

A misunderstanding of statistical power still plagues psychological sciences (Bakker,
Hartgerink, Wicherts, & van der Maas, 2016), and the effect of sample size, especially small
ones, was shown here by comparing the criterion avaliable in these analyses. Often,
individual research labs may not have the means to adequately power a proposed study.
Multilab studies and collaboration with other scientists is fundamental to alleviating these
issues, while encouraging interdisciplinary science. Collaboration increases our statistical
abilities, as every researcher cannot be expected to be proficient in all methods and analyses,
but teams of researchers can be assembled to cover a wider range of statistical skills to
provide adequate estimates of evidence in their reports. We understand that there may be

resistance to the implementation of multiple methodologies as these new methodologies take
time and effort to learn. However, through the use of free programs (JASP, R, OOM, Shiny)
and tutorials (YouTube, Coursera, http://www.statstools.com), we believe all researchers are
capable of learning these analyses. We believe that through the expansion of our analytical
knowledge and application of these new methodologies, we can begin to attenuate some of
the strain currently placed on psychological science and to increase the strength of evidence
in our discipline.

 $\begin{tabular}{ll} Table 1 \\ OOM\ Ordinal\ Pattern\ Analysis\ Example \\ \end{tabular}$ 

1	2	3	4
Individual	Time 1	Time 2	Time 3
A	3	4	5
В	4	5	2

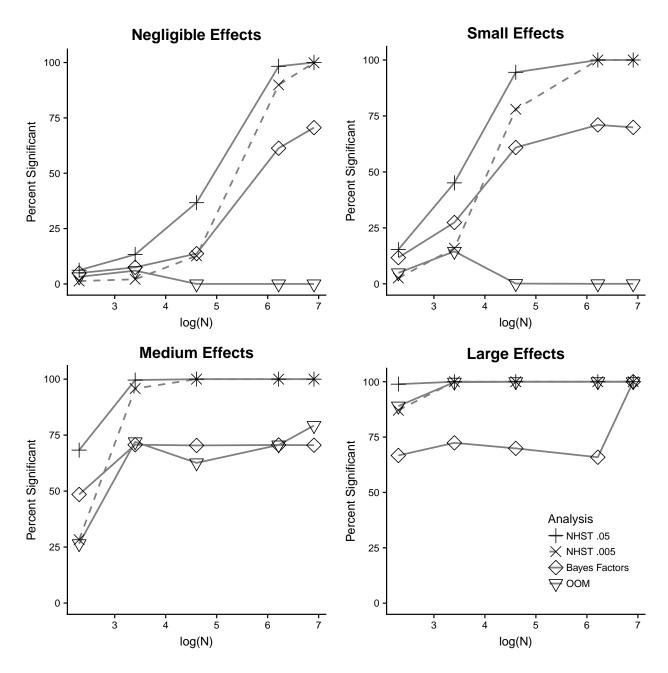

Figure 1. Percent of significant estimates at p < .05 (solid) and p < .005 (dashed) for each analysis given effect size and sample size.

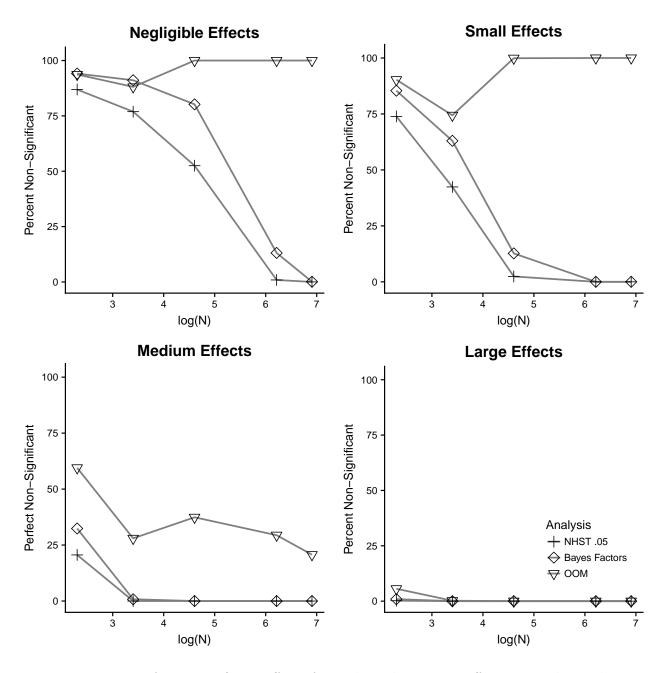

Figure 2. Percent of non-significant effects for each analysis given effect size and sample size.

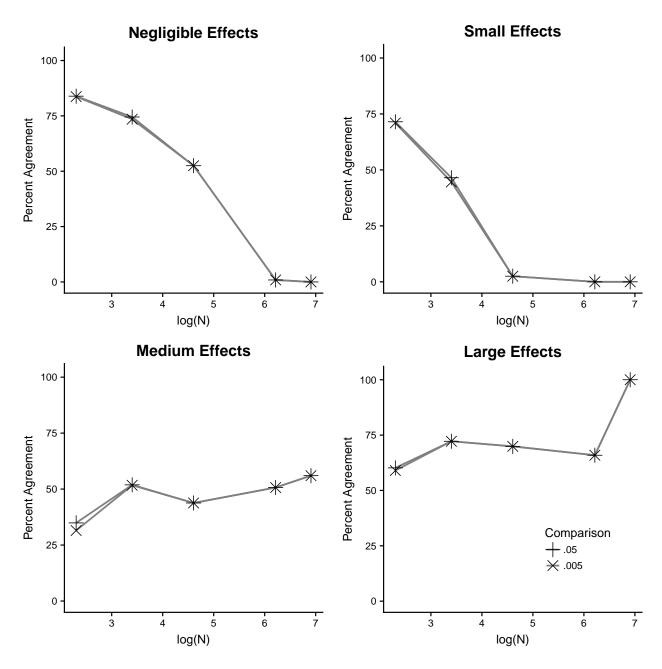

Figure 3. Percent of agreement across each analysis given effect size and sample size for omnnibus tests.

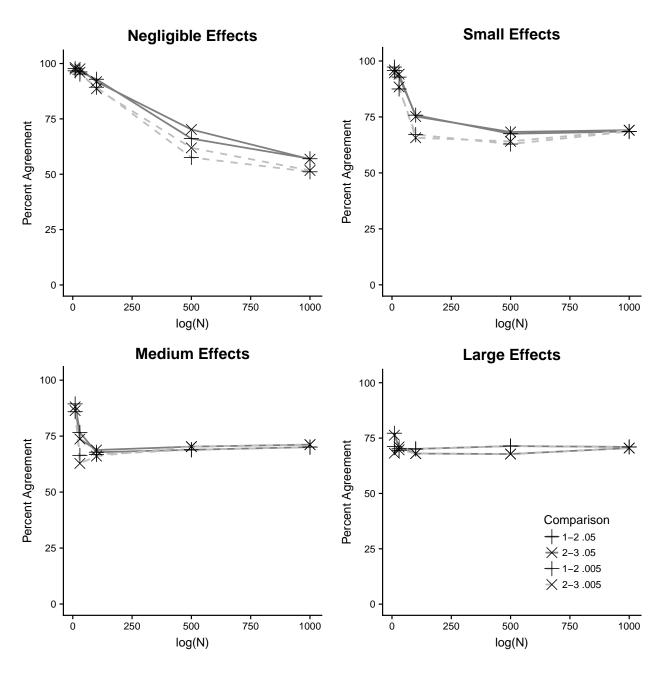

Figure 4. Percent of agreement across each analysis given effect size and sample size posthoc tests with p < .05 (solid) and p < .005 (dashed).

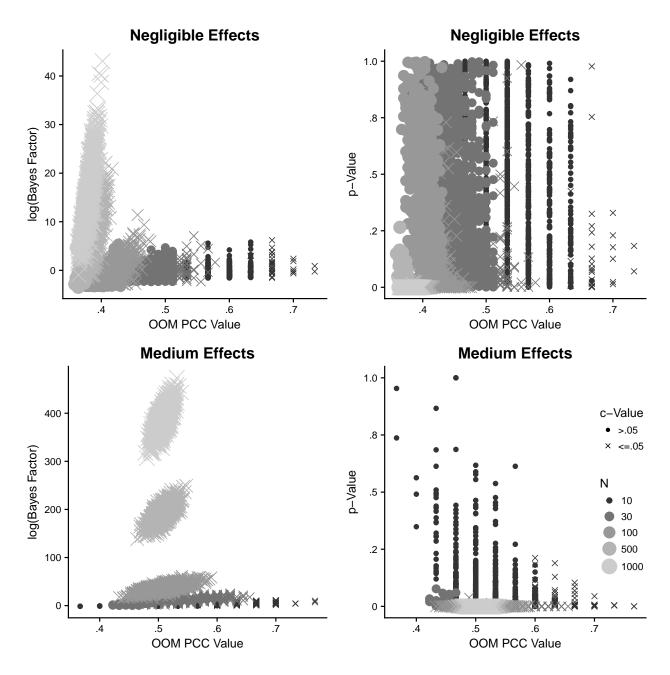

Figure 5. PCC and c-values plotted against p and BF values for negligible and medium effect size conditions. Xs indicate simulations with c-values < .05, which were binned as significant if they were found in conjunction with PCC values over .50. Point size and color indicates sample size wherein larger samples are lighter colors. Please note that the key for the entire set of graphics is in the bottom right hand corner.
