Beyond p-values: Utilizing Multiple Methods to Evaluate Evidence

2 Abstract

 $^{3}$  Null hypothesis significance testing (NSHT) is cited as a threat to validity and

 $^{4}$  reproducibility. While many individuals suggest we focus on altering the p-value at which we

<sup>5</sup> deem an effect significant, we believe this suggestion is short-sighted. Alternative procedures

6 (i.e., Bayesian analyses and Observation Oriented Modeling; OOM) can be more powerful

and meaningful to our discipline. However, these methodologies are less frequently utilized

and are rarely discussed in combination with NHST. Herein, we discuss three methodologies

(NHST, Bayesian Model comparison, and OOM), then compare the possible interpretations

of three analyses (ANOVA, Bayes Factor, and an Ordinal Pattern Analysis) in various data

environments using a frequentist simulation study. We find that changing significance

12 thresholds has little effect on conclusions. We find that evaluating multiple estimates as

evidence of an effect allows for more robust and nuanced reports of findings. These findings

suggest the need to redefine evidentiary value and reporting practices.

Beyond p-values: Utilizing Multiple Methods to Evaluate Evidence

18

Recent events in psychological science have prompted concerns within the discipline 19 regarding research practices and ultimately the validity and reproducibility of published 20 reports (Etz & Vandekerckhove, 2016; Lindsay, 2015; Open Science Collaboration, 2015; van 21 Elk et al., 2015). One often discussed matter is over-reliance, abuse, and potential hacking of 22 p-values produced by frequentist null hypothesis significance testing (NHST), as well as 23 misinterpretations of NHST results (Gigerenzer, 2004; Ioannidis, 2005; Simmons, Nelson, & Simonsohn, 2011). We agree with these concerns and believe that many before us have 25 voiced sound, generally accepted opinions on potential remedies, such as an increased focus on effect sizes (Cumming, 2008; Lakens, 2013; Maxwell, Lau, & Howard, 2015; Nosek, Spies, 27 & Motyl, 2012). However, other suggestions have been met with less enthusiasm, including a recent article by Benjamin et al. (2018) advocating that researchers should begin thinking only of p-values less than .005 as "statistically significant", thus changing  $\alpha$  levels to control Type I error rates. Additionally, Pericchi and Pereira (2016) promote the use of fluctuating  $\alpha$  levels as a function of sample size to assist with these errors. We argue it is not the threshold, or critical p, that needs to be rethought when seeking evidence, but rather if a p-value should be utilized at all, and, if so, what that p-value can tell you in relation to other indicators. While NHST and p-values may have merit, researchers have a wealth of other 35 statistical tools available to them. We believe that improvements may be made to the sciences as a whole when individuals become aware of the tools available to them and how 37 these methods may be used, either alone or in combination, to strengthen understanding and 38 conclusions. These sentiments have been shared by the American Statistical Association who 39 recently held a conference focusing on going beyond NHST, expanding their previous stance p-values (Wasserstein & Lazar, 2016). 41 Therefore, we undertook this project to show researchers how two alternative 42 paradigms compare to NHST in terms of their methodological design, statistical 43

interpretations, and comparative robustness. Herein, we will discuss the following

methodologies: NHST, Bayes Factor comparisons, and Observation Oriented Modeling. The three approaches will be compared via this simulated data using a three timepoint repeated measures design with a Likert-type scale as the outcome variable. One goal of this study is to introduce social scientists to Observation Oriented Modeling (OOM), as it is a relatively new paradigm that is readily interpretable and, as we will show, useful in these contexts. Additionally, we aim to discuss the conclusions these three methods would make given the same data, and to compare how often these methodologies agree within different data environments (i.e., given varying sample sizes and effect sizes). We hope that by discussing these methodologies in terms of a simple statistical analysis researchers will be able to easily compare and contrast methodologies. For this discussion, it is important to understand their historical background, procedural steps, and limitations, which are outlined below. After this discussion, we describe a simulation study comparing methodologies and  $\alpha$  criteria, and end with potential implications for researchers.

## **Null Hypothesis Significance Testing**

### 59 History

58

Many attribute the frequentist NHST procedure to Ronald A. Fisher (Fisher, 1932).

However, Fisher's ideas are a far cry from the NHST procedure implemented today. Fisher believed in creating one "null" hypothesis, which he described as a hypothesis to be

"nullified", or shown incorrect, not as a zero-difference hypothesis (Lehmann, 2011). He also believed that the use of any omnibus level of significance showed a "lack of statistical thinking" (Gigerenzer, Krauss, & Vitouch, 2004). He instead believed we should report the exact significance value of a test and let others make their own decision about the claims, which is more in line with the typical reporting recommendations provided by the American Psychological Association (American Psychological Association, 2010). Fisher spoke of this work to William Gosset, the man who created the Student's t-test and contributed work on the correlation coefficient (Lehmann, 2011). Gosset in turn discussed the idea of an

alternative hypothesis, a piece not included in Fisher's procedure, with decision theorist Egon Pearson.

From this discussion, Egon Pearson and Jerzy Neyman created Neyman-Pearson 73 decision theory. This theory consists of two hypotheses (i.e., null and alternative) and a binary decision criteria (i.e., significant or not, Lehmann, 1993). However, this procedure created the possibility of researcher decision errors (Dienes, 2008). A researcher may falsely 76 reject the null hypothesis (Type I error,  $\alpha$ ) or falsely fail to reject the null (Type II error,  $\beta$ ).  $\alpha$  levels set the binary decision criteria, which are used as the critical p-value for hypothesis 78 testing (i.e., p < .05), and are thus seen as evidence to reject the null hypothesis.  $\beta$  and 79 power are inherently linked (Power =  $1-\beta$ ), so as the likelihood of finding a true effect 80 increases beta decreases (Maxwell & Delaney, 2004). Although  $\alpha$  values can be chosen to be 81 quite small, and methods (such as decreasing error variance or using a one-tailed test in 82 contrast to a two-tailed test) can decrease  $\beta$  values as well, a researcher can never know if they have made the correct decision, or a decision error. Thus, Neyman and Pearson clearly 84 state that a hypothesis should not be blindly supported based solely on the estimates of one statistical test, and that replication and reproduction of results are imperative. The recent work of the Open Science Collaboration (2015) has also highlighted the need for replication studies and interpretation of results in an appropriate context. Additionally, Neyman and Pearson emphasized that use of set  $\alpha$ s and  $\beta$ s is illogical and sought instead for researchers to adjust their analysis to the needs of the particular task at hand (Gigerenzer, 2004).

## 91 Typical NHST Procedure

Neither Fisher's hypothesis testing, nor Neyman-Pearson decision theory quite match
the NSHT procedure as it is taught and applied today. Psychologists have largely adopted
an amalgamation of the two approaches. Here, we attempt to outline what we believe is the
most appropriate way to carry out the traditional NHST procedure in the context of a
repeated measures ANOVA with three levels, although we note that this set of steps is not

97 necessarily how researchers carry out the procedure in practice:

105

106

107

108

109

110

111

112

113

1) Create two hypotheses, one to be "nullified" and one "alternative" hypothesis. Within
this repeated measures framework, most researchers would define a null hypothesis  $(H_0) \text{ that indicates of all three time point population means are equal. The alternative hypothesis <math>(H_A)$  would then be that not all of the population means are equal. These can be operationalized in our example data as follows (note that for  $H_A$ , we use a common short hand to denote the model wherein any difference is hypothesized across the possible combinations of [in]equality):

$$H_0: \mu_1 = \mu_2 = \mu_3$$

$$H_A: \mu_1 \neq \mu_2 \neq \mu_3$$

- 2) Select an  $\alpha$  level that is appropriate given the context of your research, your analysis plan, and your research question, and do not blindly adopt an omnibus critical p-value (Lakens et al., 2018; Lehmann, 2011). Again, we reiterate that  $\alpha$  justification and selection is not necessarily how all researchers approach these tests.
- 3) Compute your given analysis and identify the corresponding p-value. If your p-value is less than the chosen  $\alpha$ , reject the null hypothesis and state that there appear to be differences between some of your population means; however, if your p-value is greater than or equal to the value selected, do not reject the null hypothesis, and state that a difference between the population means could not be supported.
- While the NHST procedure itself gives us testable models, the specific analysis used to
  test these models here, the repeated measures ANOVA with three levels, requires some
  additional assumptions that must be met before an analysis is begun (Tabachnick & Fidell,
  2012). Data need to have no outlying or influential observations. Data must have a normal
  sampling distribution, be linearly related, and have independent errors. Depending on the

statistical test, data must also be checked for equal variances, sphericity, and additivity.

These assumptions can be checked and, if necessary, corrected for; however, violations of
these assumptions can lead to inaccurate decisions and attenuated power. Further, with
many analysis programs, data are required to have no missing values.

While this approach is widely used, there are many limitations associated with it. 123 First, this method can be sensitive to violations of the stated assumptions, and especially, if 124 the sample size is not large enough to create a normal sampling distribution (Tabachnick & Fidell, 2012). Even if assumptions are met, or nonparametric tests are implemented (e.g., for situations where a normal distribution assumption cannot be met), this methodology does not allow a researcher to state anything about the absence of an effect (i.e., no true differences). Through traditional NHST, one can only discuss evidence regarding the 129 alternative hypothesis; one can never support the null hypothesis through this procedure. 130 Given the recent findings regarding reproducibility, showing support for the absence of an 131 effect can be even more crucial than showing support for the presence of an effect (Bakker, 132 van Dijk, & Wicherts, 2012; Lakens, 2017). 133

#### **Bayes Factors**

## 135 History

134

Thomas Bayes was a statistician and Presbyterian minister whose works are still influential today (Bellhouse, 2004). Bayes' theorem solved the inverse probability problem, namely that through the frequentist approach, one can only know the probability of data existing given a hypothesis being true, never the probability of a hypothesis being true given that the data exist (Dienes, 2008). Bayes' theorem allows one to calculate the probability of a hypothesis given some data (posterior belief) by using how probable one believes the hypothesis to be before data was collected (prior belief) and how probable one believes the data to be given one's hypothesis (likelihood). Thus, with his theorem, researchers are able to update (through the use of the likelihood) our initial beliefs (our prior) given some data

(Gelman, Carlin, Stern, & Rubin, 2013). Pierre-Simon Laplace pioneered Bayesianism and 145 advocated for a broader interpretation of this theorem (De Laplace, 1774). The use of 146 Bayesian statistics has been suggested as an NHST alternative (Dienes, 2014; Wagenmakers, 147 2007), but this approach has largely been undervalued in favor of frequentist methods as. 148 until recently, Bayesian analysis required considerable computational effort. However, today 149 we possess the technology necessary to efficiently conduct Bayesian analyses. While open 150 source software, such as R and JASP, require minimal learning to be able to effectively 151 operate (Morey & Rouder, 2015), researchers will need to invest more effort to understand 152 the focus and interpretation of Bayes Factor (BF) comparisons as they differ from traditional 153 NHST. 154

The Bayesian framework can be viewed as a continuum, with objective Bayesian 155 analyses on one end, and subjective Bayesian analyses on the other (Press, 2002). While this 156 topic could lend itself to its own manuscript, here we will simply summarize the two 157 endpoints, and discuss where our analysis may be perceived to fall on the line. Objective 158 Bayesian analysis is closest to frequentist theory, as the aim is to minimize the influence of 150 priors through the use of non-informative priors (such as Jefferys priors that are designed to 160 be invariant under reparameterization Datta & Ghosh, 1996); thus, the data are allowed to 161 maximally effect the posterior distribution. Further, objective Bayesian methods are 162 influenced by the same quality criteria that frequentist methods used, including Type I error 163 rate and power (Sellke, Bayarri, & Berger, 2001). On the other end, subjective Bayes 164 analyses include rigorously informed priors so that current knowledge can play a large role in 165 the posterior. Our current analysis splits these two; we do not utilize completely uniformed (objective) priors, as we can adjust for basic knowledge of the constraints of our data type. Given the usual lack of information about underlying distributions, a wider band of inclusion 168 was used for prior information. The BayesFactor package (Morey & Rouder, 2015) assists 169 greatly in the choice of prior and is especially user-friendly for applied researchers, as it 170 makes use of recommended default priors that have been chosen to be safe to assume under 171

a broad range of data and topics (Rouder, Morey, Speckman, & Province, 2012; Rouder,
Speckman, Sun, Morey, & Iverson, 2009). Instead of conventional F, t, and p-values, a ratio
of the likelihood of the alternative model to the null is report, usually  $BF_{10}$ . For instance,  $BF_{10} = 20$  would indicate that the effects model is favored 20 to 1 over the null model.
Conversely, if the  $BF_{10}$  were 0.10, the null model is favored 10 to 1 over the effects model.

## 177 Typical Procedure

The procedure behind BF comparisons requires two steps.

1) One must design two models for the data. For our purposes, the first of these models will be the null model, which states that there are no differences between means ( $\mu$ ; i.e., all of our observed values  $X_i$ , regardless of which time point they were assessed at  $X_{ij}$ , arise from a normal distribution N with some mean  $\mu$  and variance  $\sigma^2$ ). The second model for these analyses is the effects model, which states that each mean ( $\mu$ ) is allowed to be different from the grand mean by some amount ( $\delta$ ; as we now have observations being drawn from three potential normal distributions, all of which may have a different mean value, but the same variance). These can be operationalized as follows:

$$H_0: X_{ij} \sim N(\mu, \sigma^2)$$

$$H_A: X_{ij} \sim N(\mu + \delta_i, \sigma^2)$$

In designing these models, one must choose the prior distributions that are believed to
describe the data. Reasonable expectancies of where the data lie should be incorporated in
this decision based on previous research into the studied phenomena (Rouder et al., 2012).

2) Analyze the data given the selected priors and models. Consider the BF and use the  $BF_{10}$  as evidence of how one should update their beliefs about the models.

Based on the flexibility of the analysis, the only assumption that needs to be made is that data exists such that two competing, plausible models with different constraints may be specified.

Bayesian inference improves upon the traditional frequentist point of view by allowing 196 not only a clear interpretation of the evidence provided by the data, but also the ability to 197 speak in favor of the null hypothesis. It is important to note that while previous work has 198 indicated that p-values and BF largely agree on which hypothesis should be supported, they 199 differ in the strength of that conclusion, especially when p-values were slightly lower than  $\alpha$ 200 (i.e., .05 to .01; Wetzels et al., 2011). However, some limitations do arise in this paradigm. 201 Bayesian analyses require the researcher to take an active role in the choice of prior 202 distributions for the phenomenon they are modeling, and this decision can take some effort 203 to fully understand; however, in the meantime, there are packages such as BayesFactor that 204 provide the researcher simple default options that can readily lend themselves to many 205 research areas with little fear of being outrageous specifications. Further, unlike NHST, 206 Bayesian analyses do not necessarily control long-run error rates, as the focus is on updating 207 current model beliefs. Another concern that many researchers have is that these analyses are 208 necessarily sensitive to prior choice. However, research has shown that the choice of priors 209 has essentially no effect on conclusions when sufficient data has been collected as the priors 210 give way to the weight of the data (Klugkist & Hoijtink, 2007; Rouder et al., 2012) and when reasonable priors are considered, data are only mildly sensitive to these (Haaf & Rouder, 212 2017). Finally, many believe Bayesian analysis to be too computationally intensive to 213 complete. However, many simple programs, packages, and tutorials exist to help ease the 214 transition from frequentist to Bayesian analysis (JASP Team, 2017; Kruschke, 2014; Morey 215 & Rouder, 2015). 216

## **Observation Oriented Modeling**

James Grice argues that our problems as a science go beyond use of NHST and extend

# 218 History

217

219

into the philosophical ideas underpinning our research. Therefore, he developed a new 220 paradigm called Observation Oriented Modeling (OOM, Grice, 2011, 2014; Grice, Barrett, 221 Schlimgen, & Abramson, 2012). He reasons that by viewing psychology through the lens of philosophical realism, instead of positivism, we should be able to properly and effectively conduct research and analyze data. In contrast to positivism (i.e., which is solely concerned with finding an effect, not with how the effect occurred), philosophical realism holds that the 225 causal structure of nature can be understood through scientific investigation. The goal is 226 then to understand the causal mechanisms that give rise to the patterns observed in a given 227 set of observations, which in here would refer to data. Switching to this philosophy allows for 228 techniques that match the daily activities of social scientists in their endeavors to unravel 229 the story of how humans operate. Using OOM, a researcher does not focus on population 230 parameters and the various assumptions underlying statistical tests (e.g., random sampling, 231 normality, homogeneity of population treatment differences, etc.). 232 Generally speaking, this approach can handle any type of data, including ordinal 233 rankings and frequency counts, as all analyses are calculated in the same general fashion (see 234 Valentine & Buchanan, 2013 for an example). This simplicity occurs because OOM works on 235 the deep structure of the data. Through observational definition, the program separates 236 these units into binary code. Deep structures can be arranged to form a matrix, which can 237 then be manipulated via matrix algebra, binary Procrustes rotation, and other operations to investigate the data. The most important values from any OOM analysis are the PCC (percent correct classification) values. These values represent the summation of how well an individual's responses matched the stated or expected pattern or, in the case of causal modeling, how many of the individual's conformed to a given cause. Complete matches are 242 the proportion of observations that match the researcher-designated pattern on all

dimensions. For example, in a three-level Ordinal Pattern Analysis (OPA), a person would be tallied as a "complete match" if the ordinal pattern of his/her data matched the expected 245 ordinal pattern across all three levels. Imagine we have set a pattern that designates Time 1 246 < Time 2 < Time 3. For example, imagine we have data for two hypothetical individuals. 247 Person A has values of 3, 4, and 5 at timepoints 1, 2, and 3, respectively, while person B has 248 values of 4, 5, and 2. We can see that Person A matched the pattern completely, and 249 therefore would be counted in the PCC value. However, while person B matched the first 250 part of our pattern (time 1 less than time 2), they did not match on the third point of our 251 pattern (time 2 less than time 3); thus, they would not be counted in the PCC value. As the 252 PCC is simply the percentage of individuals in a sample whose responses match the expected 253 ordinal pattern perfectly, its computation is therefore not based on means or variances, but 254 on the basis of the observations themselves. The PCC value replaces all of the conventional 255 values for effect size used in statistical analyses. 256

The analysis we focus on here (OPA) does not form any type of linear or nonlinear
equation or regression, but simply looks for those individuals who match the expected
ordinal pattern (Grice, Craig, & Abramson, 2015). The main point of the analysis, then, is
to see how many people fit the expected pattern which is based on a causal theory. If all
causes are accounted for in the study and observations have been made with sufficient
precision and accuracy, then 100% of the persons should fit the expected pattern; otherwise,
a lower PCC value will be expected and it is up to the researcher to determine how high a
PCC must be in order to support an inference to the causal mechanism.

In OOM, traditional p-values are no longer utilized (Grice, 2011). As a secondary form
of reference value, a chance value (c-value) is obtained, which is a type of randomization test
in which the researcher determines the number of randomized trials for the test (e.g. 1,000 or
5,000 randomized versions of actual observations). This procedure is akin to permutation
tests, where PCCs are computed for the randomized data to form a distribution. The
observed PCC is then compared to these values, and the c-value (which is an empirical

probability) is determined. If the randomized data sets fit the pattern as well as or better
than the actual data does, the c-value will be high (close to 1). Low c-values (close to 0)
indicate a pattern of observations that is improbable (i.e., unlikely produced by chance)
when compared to randomized versions of the same data. Although low c-values, like low
p-values, are desirable, c-values do not adhere to a strict cut-off and should be considered a
secondary form of confirmation for the researcher that their results are distinct.

# 277 Typical Procedure

278

279

280

281

282

283

284

285

286

287

OPA is analogous to repeated measures ANOVA and contains two steps.

1) Designate the expected ranked pattern: each variable as being higher, lower, or equal to the other variables. For instance, for our analyses we defined the following pattern of individual responses  $X_i$ , whereby the first time point should be less than the second time point which should be less than the third time point. This pattern can be operationalized as follows:

$$X_{i_1} < X_{i_2} < X_{i_3}$$

2) Analyze the data using OPA. Consider the PCC (the percentage of individuals matching the ordinal hypothesis) and c-values in light of the data and use your best judgment as to whether or not the data conform to the expected pattern. This analysis only requires the assumption that the data exists such that a pattern may be designed.

As with all of these methodologies, limitations do exist. This approach is largely
concerned with patterns of responses, not with magnitudes of differences, which may be an
integral piece of information to some researchers. Unlike all approaches mentioned before, we
do not discuss the probability of some data given our hypothesis here, and instead focus on
the observed responses of the individual and how it may or may not behave as expected.

Finally, similar to the Bayesian analysis, long-run error rates are not discussed in this methodology.

## A Simulation Study

### 96 Simulated Data

295

In this study, we generated 20,000 datasets by manipulating sample size and effect size 297 for a repeated measures design with three levels. A repeated measures design was chosen as 298 it is widely used across many disciplines of psychology. These datasets were created using 299 the mytnorm package in R (Genz et al., 2017), and all code for simulations can be found at 300 https://osf.io/u9hf4/?view only=1caa9092868b4d7aadb9a83a31a979cd. Interested readers 301 can easily adapt the R code to incorporate different research designs. Likert data, ranging 302 from 1 to 7, was created by rounding mytnorm estimates to whole numbers and truncating 303 any data points out side of the appropriate range (i.e., values < 1 were rounded to 1, and 304 values > 7 were rounded to 7). We specifically chose Likert-type data as this data type is 305 one of the most common data types utilized by most social scientists. Additionally, we add 306 to the literature as other simulations have chosen to use completely continuous data (i.e., 307 simulated numbers are often precise to 10+ decimals, which is unlikely for traditional 308 sampling). The simulated data did increase in skew with this procedure from approximately 309 no skew (i.e., <0.01) to approximately 0.40 for the smallest and no effect conditions; 310 however, these values closely resembled a normal distribution with the use of mvtnorm. The 311 population means for each level were set to 2.5, 3.0, and 3.5, and pairwise effect sizes (e.g., 312 the comparison between time 1 v. time 2 and time 2 v. time 3) were manipulated by adjusting the standard deviation to create negligible effects (SD = 3.39, d = 0.10), small effects (SD = 3.00, d = 0.20), medium effects (SD = 0.50, d = 0.50), and large effects (SD = 0.50, d = 0.50)315 0.10, d = 0.80) using Cohen (1992)'s traditional guidelines for d interpretation. The smallest 316 effect size was set such that Likert style data could still be retained with the smallest 317 possible effect size. Sample size was manipulated at 10, 30, 100, 500, and 1,000 data points. 318

All combinations of the five sample sizes and four effect sizes were created, and each dataset was simulated 1,000 times, totaling 20,000 datasets.

The advantage of using mvtnorm and set SDs for each group was the ability to
approximate the assumptions of normality by randomly generating from a multivariate
normal distribution, and homogeneity by setting equal SDs for each group. In a repeated
measures design, the assumption of sphericity was met by setting the correlations between
levels in mvtnorm to zero. By maintaining the lowest level of relationship between levels, we
additionally controlled for power and examined situations of significance given the lowest
power scenario. During the data simulation, the standard deviation of the difference scores
was examined to maintain differences greater than zero, especially for low N simulations.

## 329 Analyses Performed

Descriptive Statistics. Means, mean differences between levels, and the confidence 330 intervals for each mean can be found in the complete dataset online, 331 https://osf.io/u9hf4/?view only=1caa9092868b4d7aadb9a83a31a979cd. For each simulation, 332 we also calculated d values using the standard deviation of the difference score as the 333 denominator ( $d_z$ , Lakens, 2013). The MOTE library was used to calculate the non-central 334 confidence interval for each d value as well (Buchanan, Valentine, & Scofield, 2017; 335 Cumming, 2014). This data was mainly used to determine if simulations were meeting 336 expected values overall. 337

Parametric NHST - Repeated Measures ANOVA. Repeated measures
ANOVA using the ezANOVA() function in the ez library was utilized with type three sum of
squares (Lawrence, 2017). This style of ANOVA is used to compare the same individuals
across multiple or all conditions in an experiment. The null hypothesis states that there are
no significant differences between population means, and the research hypothesis posits that
there are differences between some population means, but does not specify which population
means may differ, just that one or more will differ as the alternative. This test uses the F

distribution focusing on p values.

To determine where differences may exist, post hoc dependent t-tests are normally 346 analyzed in the event of a significant F-ratio. We did not run all pairwise comparisons, 347 instead focusing on the linear trend simulated by comparing level one to two and level two to 348 three. This set of comparisons also controlled the effect size between comparisons, as 349 comparing level one to three would have doubled the effect size. However, we assumed that 350 typical researchers might compare all three pairwise combinations in practice and used a 351 Bonferroni correction across all three possible pairwise combinations to calculate p values for 352 post hoc tests. Therefore, while we only discuss the two comparisons, we utilized the more 353 stringent cutoff of the Bonferroni correction as we believe this procedure would be how the 354 majority of researchers would handle the data. Interested readers can find all three 355 comparison values in the complete dataset online. Following traditional usage, a p-value of 356 less than .05 was binned as significant, whereas p-values ranging from .10 to .05 were binned 357 as marginally significant. Any p-values larger than .10 were binned as non-significant. A 358 second set of p-value comparisons was calculated given Benjamin et al. (2018)'s suggestion 359 to change  $\alpha$  criterion to less than .005. Any p-value less than .005 was binned as significant, while data ranging from .005 to .10 was marginal or suggestive, and p > .10 was non-significant. 362

Bayesian Analysis: Bayes Factor. We compared a null model with one grand mean for all three levels to an effects model wherein means were allowed to differ using the BayesFactor package (Morey & Rouder, 2015). The default in this package is a Jeffreys prior with a fixed rscale (0.5) and random rscale (1.0). BF were calculated, and follow up t-test BFs were computed for the same two comparisons as in the previous models using default priors from the BayesFactor package (e.g., Jeffreys prior for population variance, Cauchy prior for standardized effect size). To compare Bayesian results to other statistical methods, we used recommendations from Kass and Raftery (1995) to bin results into weak evidence (BFs < 3), positive evidence (e.g., akin to marginal p-values, BFs = 3-20), and strong

evidence (BFs > 20). We must stress here that BF interpretation should focus on 372 understanding the odds of model ratios, not necessarily the presence or absence of an effect. 373 However, given that we wanted to compare the conclusions one would reach given this data 374 in a Bayesian paradigm to that of a frequentist paradigm, these bins are used as a convenient 375 comparison to the frequentist procedures using set criteria for interpretation (Morey, 2015). 376 Should any reader become curious how a different set of binning values affect our analyses, 377 all code and data are at their disposal at 378 https://osf.io/u9hf4/?view only=1caa9092868b4d7aadb9a83a31a979cd, and this manuscript 379 was written with the papaja package allowing one to view the code inline with this text 380 (Aust & Barth, 2017). 381

**OOM: Ordinal Pattern Analysis.** An R script of the Ordinal Pattern Analysis 382 from Grice et al. (2015)'s OOM program was provided from Sauer and Luebke (2016). We 383 set the expected ranked pattern as level one less than level two less than level three. Once 384 this pattern was defined, we then analyzed the data to see if each individual's set of 385 observations matched this expected ordinal pattern. PCC values were generated, and 386 c-values were computed by randomizing the data 1,000 times. Solely for purposes of 387 comparison, we used the following significance coding schema: significant studies had a high 388 PCC value (.50 < PCC < 1.00) and a low c-value (c < .05), marginal studies had a high 389 PCC value and a moderate c-value (.05 < c < .10), and non-significant studies had low PCC 390 values (PCC < .50), regardless of their c-values. Again, we must stress that this paradigm eschews binning estimates and that our use of bins was a) discussed and decided upon before data analysis, and b) created only for the purposes of comparing this new methodologies 393 possible conclusions to that of a frequentist framework. We welcome interested readers to 394 explore the data more, defining their own bins and viewing the affects, by viewing and 395 editing our code online. 396

For all simulations, we first binned the estimates into significant, marginal, and

Results

### Percent of Estimates

399

non-significant effect categories as described in the Analyses Performed section above. Next, 400 we calculated the percentage of these analyses that would be classified into each of these 401 categories, separated about by statistical analysis, sample size, and effect size. These 402 estimates were binned across both the overall and follow up post hoc tests, and the combined 403 data are presented for this analysis. Since all three categories of binning total to 100%, we present only the significant and non-significant results. Significant critical omnibus estimates 405 are presented in Figure 1. All figures discussed in this manuscript may be viewed as 406 interactive graphics on our OSF page through a provided Shiny app. In Figures with sample 407 size on the axes, we log transformed N to allow for visual distinction between sample sizes, 408 as smaller N values were compressed when using the N=10 to 1000 on the axis. Both N 409 and  $\log(N)$  can be found in the Shiny app, along with the ability to zoom in to specific 410 ranges of sample size. 411 For negligible effects at p < .05 (solid lines), we found that NSHT analyses showed a 412 predictable Type I error bias, in that they detected significant estimates with extremely 413 small d values as sample size increased. Binned BF values showed a similar pattern, but 414 were more conservative with less percent significant estimates. OOM analyses were the most 415 conservative, essentially never detecting an estimate in the negligible effect simulations. 416 Small effect sizes showed the same pattern for NHST, BF, and OOM results, with the 417 proportion of significant estimates increasing more rapidly and asymptoting at a smaller sample size than negligible effects. At medium effect sizes, NHST analyses nearly always 419 detected significant estimates, while BF and OOM analyses would have been considered significant around 75% of the time. Interestingly, with large effect sizes, OOM analyses 421 mirrored NHST by always detecting estimates, and BF analyses were generally more 422 conservative except at the largest sample size. Figure 1's dashed lines indicate the results if 423

values were binned at p < .005, and the differences between these results were very subtle. Lowering  $\alpha$  reduced the number of significant estimates at small N values for all four effect sizes, with more pronounced differences at negligible and small effect sizes. However, the graphs converged to the same conclusion that large enough sample sizes could produce significant results at negligible and small effect sizes.

Figure 2 portrays the results for non-significant binned simulations, which were the 429 same for both  $\alpha$  criterion. Across all effect sizes, BF and NHST showed similar results, 430 where non-significant estimates were detected at lower sample sizes for negligible and small 431 effect size simulations. At medium and large effect sizes, almost all estimates would have 432 been considered significant, therefore, detection rates for non-significant estimates were 433 around zero. OOM displayed a conservative set of findings, showing nearly 100% 434 non-significant estimates at negligible and small effect sizes (mirroring results from Figure 1). 435 At medium effect sizes, approximately a quarter of estimates were non-significant, 436 illustrating the conservative nature of OOM interpretations. 437

Figure 3 depicts the relationship between the effect size of time 1 minus time 2 and the 438 corresponding PCC values. These metrics appear to represent different concepts where effect 439 size measures the magnitude of the difference between two data points while PCC disregards 440 magnitude and represents the proportion of the sample following the given ordinal pattern across all three time points. Given these differences, it is interesting how well these two 442 measures converge together. As sample size increases, estimates for both d and PCC become 443 more precise (i.e., smaller range, closer to the simulated effect size). We believe that PCC offers researchers the ability not only to confirm that their effect size is reasonable, but also to better understand the pattern their data are following, especially if an observed effect size contradicts previous literature. For example, let us assume there is previous literature that states that a small positive effect exists, such that responses should increase from time 1 to time 2. Under conditions of a true small effect (d=-0.20) and sample size of 30, our graph 449 shows us that it is possible to obtain a positive medium effect size (d = 0.50; indicating the 450

time 1 is more extreme than time 2). Upon finding these contradicting results, the researcher could further seek to understand the pattern their data are following by computing the PCC value for the experiment. The PCC value for this example would be above .50, indicating that, in over half of respondents the values for time 1 are less than time 2 (in turn less than time 3, as it measures the entire pattern), even though magnitude of change suggests that time 1 is larger than time 2. This gives the researcher a richer piece of information, which can help to describe their results in a more nuanced fashion.

# 458 Percent Agreement

A goal of this project was to expand the toolbox of options for researchers to determine 450 what evidence supports their hypotheses by examining multiple methodologies. We 460 calculated the percent of time that all analyses agreed across overall and post hoc comparison 461 estimates. Figure 4 illustrates the pattern of 100% agreement on effects for critical omnibus 462 tests only at each sample size and effect size. Figure 5 portrays the results for post hoc tests, 463 which only uses NHST and Bayes Factor analyses, as OOM does not have a post hoc test (i.e., the test is a pattern analysis that presupposes the expected direction of post hoc tests). When effect sizes were negligible and for small effects, agreement was best across small 466 samples and decreased across sample size, as NHST was overly biased to report significant 467 estimates and OOM and BF were less likely to do so. For medium and large effect sizes, 468 50-75% agreement was found, usually regardless of sample size. Additionally, we found that 469 for negligible, small, and medium effects, agreement for post hoc tests was higher than 470 agreement for overall comparisons. The post hoc comparisons for levels 1 to 2 and levels 2 to 3 were less likely to be binned as significant across negligible and small effects, so the 472 agreement levels were higher for these individual comparisons due to non-significant follow up tests. The critical omnibus test was more likely to be significant due to the inclusion of effect of comparisons between level 1 and 3, which were double the effect size. However, 475 these post hoc comparisons do not include the conservative significant binning from OOM,

which decreased critical omnibus 100% agreement seen in Figure 4. Again, the differences between p < .05 and p < .005 were minimal. Complete tables of percentages of binning across critical omnibus and post hoc tests, along with agreement percentages broken down by bins can be found at https://osf.io/u9hf4/?view\_only=1caa9092868b4d7aadb9a83a31a979cd.

## 81 Criterion Comparison

As the relationship between BF and p-values is already well documented, we will not 482 discuss them here beyond stating that we found the expected pattern shown in previous 483 work (Rouder et al., 2012), and that individuals who wish to view this comparison, as well as 484 all the other comparisons discussed here should visit our interactive Shiny application at our 485 OSF page. Of interest was the comparison of OOM indices to traditional NHST and 486 Bayesian indices. First, in Figure 6, PCC values are plotted against log BF values and 487 p-values. The log of BF was taken to include all values on a viewable axis, and all infinity values were windsorized to the next highest point. Increasing sample size is shown by 489 increasing point size and lighter colors. Additionally, since OOM values are a combination of PCC and c-values, c-values below .05 are shown as Xs instead of dots. Therefore, all values PCC >= .50 that are also denoted as Xs would be considered significant in this example. The provided Shiny application uses color to distinguish sample size differences, as well as 493 includes options to create each combination effect size and criterion individually. Only two graphs are provided here to save space. 495 In Figure 6, the left hand column portrays the relationship between log BF values and 496 PCC values in negligible and medium effect sizes. With negligible effect sizes, we found large variability in PCC values across a small span of BF values while sample sizes remained low, but as N increased, we saw that the range of PCC values narrowed considerably with increasing BF values. Therefore, as sample size increased, the PCC values constricted, while 500 BF values expanded. A similar pattern appeared when viewing the medium sample size 501 graph, as again PCC values became less variable with increased sample size, and BF tended 502

to increase both in variability and in value as the sample size grew. Here, we can see a benefit of PCC, along with c-values, as increasing sample size portrayed more precision in PCC, instead of the increased variability found in BF.

It is also important to note that within the negligible effects graph, while many of 506 these PCC values reached high values, that these values did not denote patterns that would 507 necessarily be seen as unique. c-values were a secondary measure of evaluation that 508 eliminated a number of these matches from being considered meaningful. A large majority of 509 points with larger sample sizes on the figure included low chance values, however, the PCC 510 values for these simulations were lower than a meaningful percent used for cutoff criterion. 511 This two-step process helped to weed out effects that were negligible, especially at larger 512 sample sizes. 513

Additionally, we compared p-values and PCC values, which are illustrated on the right 514 hand side of Figure 6. Again, PCC values showed far more variability with small sample 515 sizes, and the p-values associated with these smaller sample sizes were also quite variable. 516 Importantly, even when an effect was negligible, PCC values become less variable with 517 increasing sample size. PCC values also indicated that there was little evidence of the 518 hypothesized pattern by shifting toward zero. p-values decreased in variability at high 519 sample sizes and shifted toward minuscule values, thus, pointing toward rejecting the null 520 hypothesis. With medium effect sizes, both p-values and PCC values were variable at small 521 sample sizes. At larger sample sizes, p-values decreased towards floor effects (i.e., closer to 522 zero), while PCC values simply narrowed in range shifting slight above .50. The benefit of 523 multiple criteria evaluation here was clear, as p-values increasingly indicated significance as sample size increased, PCC values were not effected in this way and thus presented a more stable picture of the presence of an effect. While multiple criteria may not completely reduce the interpretation of false positives in the literature, the relationship between these values 527 illustrated that multiple indices can provided a clearer picture of the evidentiary value 528 available in a study. 529

### Limitations

Within any study a number of limitations exist. The largest limitation of our study is 531 that we chose to focus on a simple three level repeated measures ANOVA design. The 532 benefit to this focus is the simplicity of understanding the relationship between analyses, 533 while also using a well understood NHST procedure. However, is possible that these same 534 relationships may or may not exist in alternative design contexts. Additionally, our choices 535 for classification of significant effects for p-values, BF, PCC, and c-values was based on what 536 we believe a reasonable researcher may designate; however, these classifications may vary in 537 the real world. We provide open access to our simulations and code so that an interested 538 party can tinker with these choices. We believe the global conclusions would likely be similar 539 across changes, however, the specific percentages and patterns would likely differ. Finally, due to the specification of our simulation we did not violate any statistical assumptions. It is possible that the violation of these assumptions may cause changes in the relationships we see here.

544 Discussion

This manuscript was designed to showcase two alternative paradigms to NHST 545 researchers and to compare the conclusions these alternative methodologies might make in a given data environment to those NHST would make. We believe that the awareness of 547 multiple methodologies might assist in strengthening our conclusions and improving 548 reproducibility by giving researchers the ability to identify an optimal method given the question at hand. Further, we believe that should a researcher utilize multiple methodologies (e.g., analyzing and reporting both a NHST p-value as well as an OOM PCC value) that these estimates in tandem can help readers to weight these various forms of evidence and 552 arrive at a more robust conclusion. We found that changing the threshold at which p-values 553 are deemed significant had little to no effect on conclusions, especially at large sample sizes, 554 regardless of effect size. This finding is notable as the article by Benjamin et al. (2018) 555

states that an increase in sample size is likely to decrease false positives "by factors greater than two" (p. 10), and work by Pericchi and Pereira (2016) state that an adaptive level of significance would be beneficial in these circumstances—neither of which are not supported by our simulations. Our science will not grow by moving the significance line in the sand, as this line has already been shown to have "no ontological basis" (Rosnow & Rosenthal, 1989, p. 1277).

Instead, we need to embrace the multitude of perspectives available to us and to begin 562 to employ these diverse approaches. While NHST can still serve us well when properly 563 utilized, it is important for researchers to understand that different methods seek to answer 564 different questions, and that we need to ensure that we are using the right method to answer 565 a given question. When evaluating evidence in order to answer these questions we must be 566 wary of looking for significant differences and focus instead on finding meaningful differences. 567 By combining these approaches we may be better able to qualify the strength of our evidence 568 and discuss a more nuanced version of our data. Additionally, while all of these methods 569 have drawbacks, when used in combination these methods can begin to overcome many of 570 these limitations. For instance, given a large sample size, we would expect BF values to be 571 very large and p-values to be very small, both indicating that the null model/hypothesis should not be supported. However, if we also have a PCC value of .30, we may decide that it 573 is possible that this effect is very small and possibly negligible. This multifaceted approach can help to curb our enthusiasm over small or negligible "significant" effects that may not be 575 practically meaningful and possibly may not replicate. Regardless if analyses agree or 576 disagree on the presence of an effect, a researcher can investigate the direction and size of 577 the effect, the proportion of data that agrees or disagrees with the direction of the effect, and 578 discuss conclusions accordingly. Each methodology behaves slightly differently in given data 579 environments, which might begin to highlight meaningful differences when discussed together. 580

Some may contest that all of these analyses are capable of being hacked, like p-values, through researcher degrees of freedom, choice of priors, or pattern choice, among other

581

582

actions (Simmons et al., 2011). Transparency throughout the research process is key to 583 eliminating these issues, as  $\alpha$  changes may only encourage bad research practices with the 584 current incentive structure on publishing. Although we have the capability to share research 585 across the world, research often still occurs behind closed doors. The Open Science 586 Framework grants insight into research processes, allowing researchers to share their 587 methodologies, code, design, and other important components of their projects. In addition 588 to posting materials for projects, pre-registration of hypotheses and methodology will be an 580 important facet in scientific accountability. Further, with increased transparency editors and 590 other researchers can weigh the evidence presented according to their own beliefs. 591

Our key suggestion in this project is the redefinition of evidentiary value. The current 592 focus on p-values has shown to be problematic, as many of the studies from the Open 593 Science Collaboration (2015) do not replicate at p < .05 or p < .005 (Lakens et al., 2018). 594 With the change in transparency mentioned above, publishing research with solid research 595 designs and statistics, regardless of p-values, will allow for a broader range of evidence to 596 become available. Publishing null findings is critical in replication and extension for 597 discovering the limits and settings necessary for phenomena. Registered replications and 598 reports will allow studies to be accepted prior to results being known, thus allowing researchers to focus on experimental design and hypotheses apriori instead of p-values post hoc. Reports should describe multiple indicators of evidence, such as effect sizes, confidence intervals, power analyses, Bayes Factors, and other descriptive statistics (Finkel, Eastwick, & 602 Reis, 2015; Nosek & Lakens, 2014; van't Veer & Giner-Sorolla, 2016). 603

A misunderstanding of statistical power still plagues psychological sciences (Bakker,
Hartgerink, Wicherts, & van der Maas, 2016), and the effect of sample size, especially small
ones, was shown here by comparing the criterion available in these analyses. Often,
individual research labs may not have the means to adequately power a proposed study.
Multilab studies and collaboration with other scientists is fundamental to alleviating these
issues, while encouraging interdisciplinary science. Collaboration increases our statistical

abilities, as every researcher cannot be expected to be proficient in all methods and analyses, 610 but teams of researchers can be assembled to cover a wider range of statistical skills to 611 provide adequate estimates of evidence in their reports. We understand that there may be 612 resistance to the implementation of multiple methodologies as these new methodologies take 613 time and effort to learn. However, through the use of free programs (JASP, R, OOM, Shiny) 614 and tutorials (YouTube, Coursera, http://www.statstools.com), we believe all researchers are 615 capable of learning these analyses. We believe that through the expansion of our analytical 616 knowledge and application of these new methodologies, we can begin to attenuate some of 617 the strain currently placed on psychological science and to increase the strength of evidence 618 in our discipline. 619

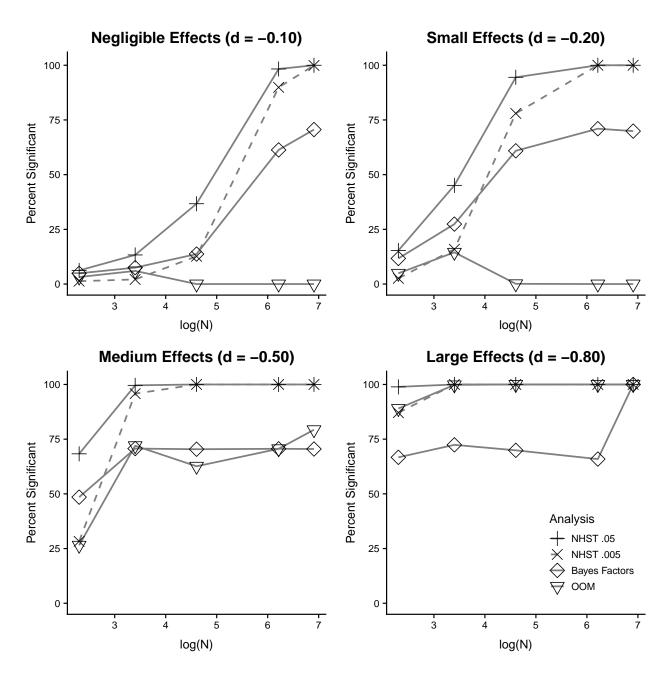

Figure 1. For NHST analyses only, percent of significant estimates at p < .05 (solid) and p < .005 (dashed) for each analysis given effect size and sample size.

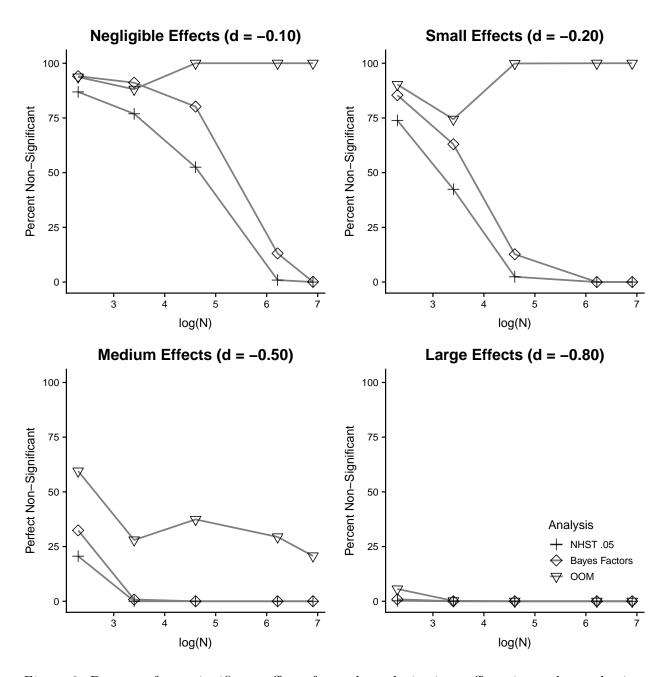

Figure 2. Percent of non-significant effects for each analysis given effect size and sample size.

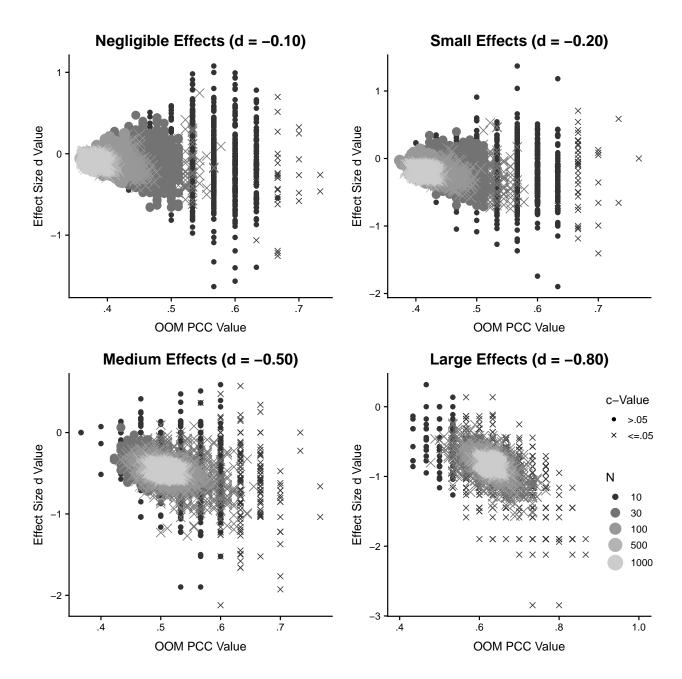

Figure 3. PCC and c-values plotted against observed effect size (d-values) given effect size and sample size conditions. Xs indicate simulations with c-values < .05, which were binned as significant if they were found in conjunction with PCC values over .50. Point size and color indicates sample size wherein larger samples are lighter colors. Please note that the key for the entire set of graphics is in the bottom right hand corner.

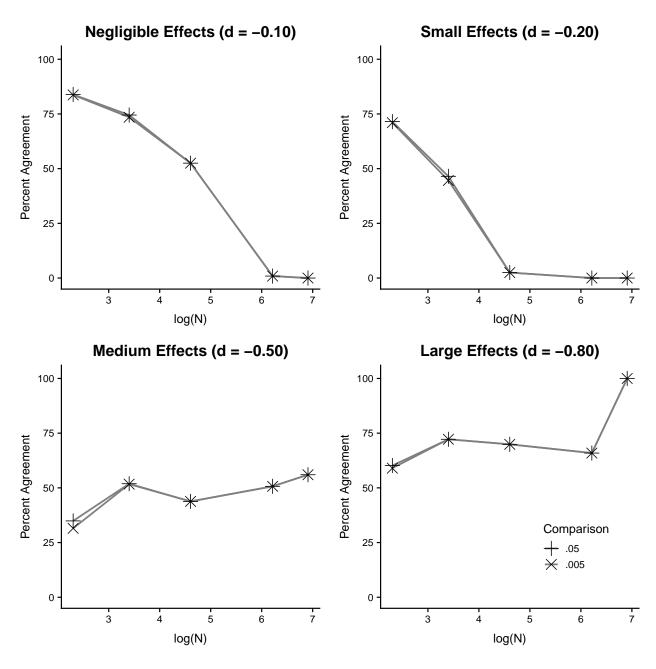

Figure 4. Percent of agreement across all analyses given effect size and sample size for omnnibus tests.

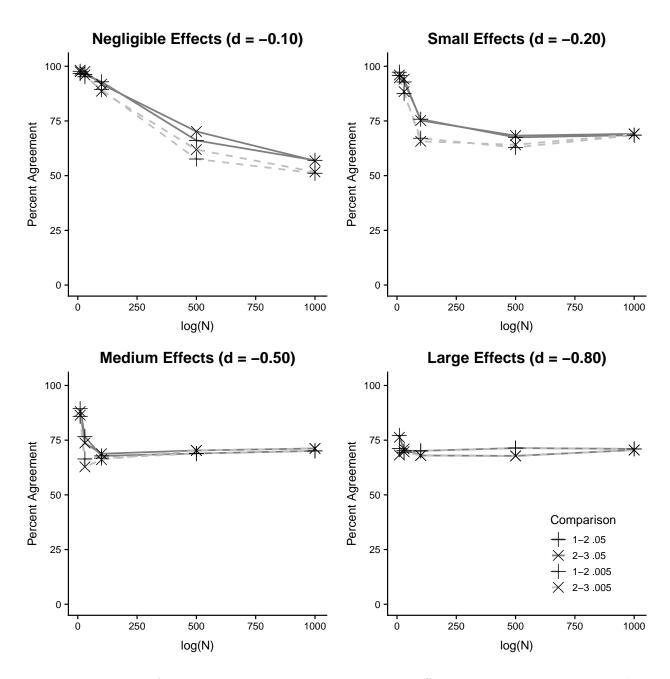

Figure 5. Percent of agreement across each analysis given effect size and sample size posthoc tests with p < .05 (solid) and p < .005 (dashed). Note that this graph only compares the NHST and BF conclusions.

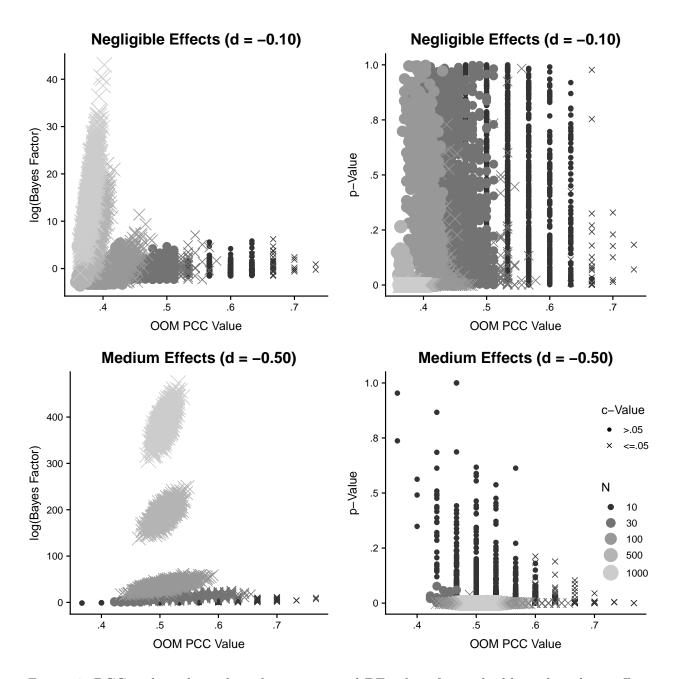

Figure 6. PCC and c-values plotted against p and BF values for negligible and medium effect size conditions. Xs indicate simulations with c-values < .05,which were binned as significant if they were found in conjunction with PCC values over .50. Point size and color indicates sample size wherein larger samples are lighter colors. Please note that the key for the entire set of graphics is in the bottom right hand corner.
