Beyond p-values: Utilizing Multiple Methods to Evaluate Evidence

Abstract 2

Null hypothesis significance testing (NSHT) is cited as a threat to validity and

reproducibility. While many individuals suggest we focus on altering the p-value at which we

deem an effect significant, we believe this suggestion is short-sighted. Alternative procedures

(i.e., Bayesian analyses and Observation Oriented Modeling; OOM) can be more powerful

and meaningful to our discipline. However, these methodologies are less frequently utilized

and are rarely discussed in combination with NHST. Herein, we discuss three methodologies

(NHST, Bayesian Model comparison, and OOM), then compare the possible interpretations

of three analyses (ANOVA, Bayes Factor, and an Ordinal Pattern Analysis) in various data 10

environments using a frequentist simulation study. We find that changing significance 11

thresholds has little effect on conclusions. We find that evaluating multiple estimates as 12

evidence of an effect allows for more robust and nuanced reports of findings. These findings 13

suggest the need to redefine evidentiary value and reporting practices. 14

Modeling, evidence

Beyond p-values: Utilizing Multiple Methods to Evaluate Evidence

17

Recent events in psychological science have prompted concerns within the discipline 18 regarding research practices and ultimately the validity and reproducibility of published 19 reports (Etz & Vandekerckhove, 2016; Lindsay, 2015; Open Science Collaboration, 2015; van 20 Elk et al., 2015). One often discussed matter is over-reliance, abuse, and potential hacking of 21 p-values produced by frequentist null hypothesis significance testing (NHST), as well as 22 misinterpretations of NHST results (Gigerenzer, 2004; Ioannidis, 2005; Simmons, Nelson, & Simonsohn, 2011). We agree with these concerns and believe that many before us have voiced sound, generally accepted opinions on potential remedies, such as an increased focus on effect sizes (Cumming, 2008; Lakens, 2013; Maxwell, Lau, & Howard, 2015; Nosek, Spies, & Motyl, 2012). However, other suggestions have been met with less enthusiasm, including a recent article by Benjamin et al. (2018) advocating that researchers should begin thinking only of p-values less than .005 as "statistically significant", thus changing α levels to control 29 Type I error rates. Additionally, Pericchi and Pereira (2016) promote the use of fluctuating α levels as a function of sample size to assist with these errors. We argue it is not the 31 threshold, or critical p, that needs to be rethought when seeking evidence, but rather if a 32 p-value should be utilized at all, and, if so, what that p-value can tell you in relation to other 33 indicators. While NHST and p-values may have merit, researchers have a wealth of other statistical tools available to them. We believe that improvements may be made to the 35 sciences as a whole when individuals become aware of the tools available to them and how these methods may be used, either alone or in combination, to strengthen understanding and conclusions. These sentiments have been shared by the American Statistical Association who recently held a conference focusing on going beyond NHST, expanding their previous stance p-values (Wasserstein & Lazar, 2016).

Therefore, we undertook this project to show researchers how two alternative paradigms compare to NHST in terms of their methodological design, statistical

interpretations, and comparative robustness. Herein, we will discuss the following methodologies: NHST, Bayes Factor comparisons, and Observation Oriented Modeling. The three approaches will be compared via this simulated data using a three timepoint repeated 45 measures design with a Likert-type scale as the outcome variable. One goal of this study is to introduce social scientists to Observation Oriented Modeling (OOM), as it is a relatively 47 new paradigm that is readily interpretable and, as we will show, useful in these contexts. Additionally, we aim to discuss the conclusions these three methods would make given the same data, and to compare how often these methodologies agree within different data environments (i.e., given varying sample sizes and effect sizes). We hope that by discussing 51 these methodologies in terms of a simple statistical analysis researchers will be able to easily compare and contrast methodologies. For this discussion, it is important to understand their historical background, procedural steps, and limitations, which are outlined below. After this discussion, we describe a simulation study comparing methodologies and α criteria, and end with potential implications for researchers.

Null Hypothesis Significance Testing

8 History

57

Many attribute the frequentist NHST procedure to Ronald A. Fisher (Fisher, 1932).

However, Fisher's ideas are a far cry from the NHST procedure implemented today. Fisher believed in creating one "null" hypothesis, which he described as a hypothesis to be "nullified", or shown incorrect, not as a zero-difference hypothesis (Lehmann, 2011). He also believed that the use of any omnibus level of significance showed a "lack of statistical thinking" (Gigerenzer et al., 2004). He instead believed we should report the exact significance value of a test and let others make their own decision about the claims, which is more in line with the typical reporting recommendations provided by the American Psychological Association (American Psychological Association, 2010). Fisher spoke of this

work to William Gosset, the man who created the Student's *t*-test and contributed work on the correlation coefficient (Lehmann, 2011). Gosset in turn discussed the idea of an alternative hypothesis, a piece not included in Fisher's procedure, with decision theorist Egon Pearson.

From this discussion, Egon Pearson and Jerzy Neyman created Neyman-Pearson 72 decision theory. This theory consists of two hypotheses (i.e., null and alternative) and a 73 binary decision criteria (i.e., significant or not, Lehmann, 1993). However, this procedure created the possibility of researcher decision errors (Dienes, 2008). A researcher may falsely 75 reject the null hypothesis (Type I error, α) or falsely fail to reject the null (Type II error, β). 76 α levels set the binary decision criteria, which are used as the critical p-value for hypothesis 77 testing (i.e., p < .05), and are thus seen as evidence to reject the null hypothesis. β and 78 power are inherently linked (Power = $1-\beta$), so as the likelihood of finding a true effect 79 increases beta decreases (Maxwell & Delaney, 2004). Although α values can be chosen to be quite small, and methods (such as decreasing error variance or using a one-tailed test in contrast to a two-tailed test) can decrease β values as well, a researcher can never know if they have made the correct decision, or a decision error. Thus, Neyman and Pearson clearly state that a hypothesis should not be blindly supported based solely on the estimates of one statistical test, and that replication and reproduction of results are imperative. The recent work of the Open Science Collaboration (2015) has also highlighted the need for replication studies and interpretation of results in an appropriate context. Additionally, Neyman and Pearson emphasized that use of set α s and β s is illogical and sought instead for researchers to adjust their analysis to the needs of the particular task at hand (Gigerenzer, 2004). 89

90 Typical NHST Procedure

Neither Fisher's hypothesis testing, nor Neyman-Pearson decision theory quite match the NSHT procedure as it is taught and applied today. Psychologists have largely adopted

an amalgamation of the two approaches. Here, we attempt to outline what we believe is the most appropriate way to carry out the traditional NHST procedure in the context of a repeated measures ANOVA with three levels, although we note that this set of steps is not necessarily how researchers carry out the procedure in practice:

1) Create two hypotheses, one to be "nullified" and one "alternative" hypothesis. Within this repeated measures framework, most researchers would define a null hypothesis (H_0) that indicates of all three time point population means are equal. The alternative hypothesis (H_A) would then be that not all of the population means are equal. These can be operationalized in our example data as follows (note that for H_A , we use a common short hand to denote the model wherein any difference is hypothesized across the possible combinations of [in]equality):

$$H_0: \mu_1 = \mu_2 = \mu_3$$

$$H_A: \mu_1 \neq \mu_2 \neq \mu_3$$

- 2) Select an α level that is appropriate given the context of your research, your analysis plan, and your research question, and do not blindly adopt an omnibus critical p-value (Lakens et al., 2018; Lehmann, 2011). Again, we reiterate that α justification and selection is not necessarily how all researchers approach these tests.
- 3) Compute your given analysis and identify the corresponding p-value. If your p-value is less than the chosen α , reject the null hypothesis and state that there appear to be differences between some of your population means; however, if your p-value is greater than or equal to the value selected, do not reject the null hypothesis, and state that a difference between the population means could not be supported.
- While the NHST procedure itself gives us testable models, the specific analysis used to test these models here, the repeated measures ANOVA with three levels, requires some

additional assumptions that must be met before an analysis is begun (Tabachnick & Fidell, 2012). Data need to have no outlying or influential observations. Data must have a normal sampling distribution, be linearly related, and have independent errors. Depending on the statistical test, data must also be checked for equal variances, sphericity, and additivity. These assumptions can be checked and, if necessary, corrected for; however, violations of these assumptions can lead to inaccurate decisions and attenuated power. Further, with many analysis programs, data are required to have no missing values.

While this approach is widely used, there are many limitations associated with it. 122 First, this method can be sensitive to violations of the stated assumptions, and especially, if 123 the sample size is not large enough to create a normal sampling distribution (Tabachnick & 124 Fidell, 2012). Even if assumptions are met, or nonparametric tests are implemented (e.g., for 125 situations where a normal distribution assumption cannot be met), this methodology does 126 not allow a researcher to state anything about the absence of an effect (i.e., no true 127 differences). Through traditional NHST, one can only discuss evidence regarding the 128 alternative hypothesis; one can never support the null hypothesis through this procedure. Given the recent findings regarding reproducibility, showing support for the absence of an effect can be even more crucial than showing support for the presence of an effect (Bakker, 131 van Dijk, & Wicherts, 2012; Lakens, 2017). 132

Bayes Factors

34 History

133

Thomas Bayes was a statistician and Presbyterian minister whose works are still influential today (Bellhouse, 2004). Bayes' theorem solved the inverse probability problem, namely that through the frequentist approach, one can only know the probability of data existing given a hypothesis being true, never the probability of a hypothesis being true given

that the data exist (Dienes, 2008). Bayes' theorem allows one to calculate the probability of 139 a hypothesis given some data (posterior belief) by using how probable one believes the 140 hypothesis to be before data was collected (prior belief) and how probable one believes the 141 data to be given one's hypothesis (likelihood). Thus, with his theorem, researchers are able 142 to update (through the use of the likelihood) our initial beliefs (our prior) given some data 143 (Gelman, Carlin, Stern, & Rubin, 2013). Pierre-Simon Laplace pioneered Bayesianism and 144 advocated for a broader interpretation of this theorem (De Laplace, 1774). The use of 145 Bayesian statistics has been suggested as an NHST alternative (Dienes, 2014; Wagenmakers, 2007), but this approach has largely been undervalued in favor of frequentist methods as, 147 until recently, Bayesian analysis required considerable computational effort. However, today 148 we possess the technology necessary to efficiently conduct Bayesian analyses. While open 149 source software, such as R and JASP, require minimal learning to be able to effectively operate (Morey & Rouder, 2015), researchers will need to invest more effort to understand 151 the focus and interpretation of Bayes Factor (BF) comparisons as they differ from traditional 152 NHST. 153

The Bayesian framework can be viewed as a continuum, with objective Bayesian 154 analyses on one end, and subjective Bayesian analyses on the other (Press, 2002). While this 155 topic could lend itself to its own manuscript, here we will simply summarize the two 156 endpoints, and discuss where our analysis may be perceived to fall on the line. Objective 157 Bayesian analysis is closest to frequentist theory, as the aim is to minimize the influence of 158 priors through the use of non-informative priors (such as Jefferys priors that are designed to 159 be invariant under reparameterization Datta & Ghosh, 1996); thus, the data are allowed to maximally effect the posterior distribution. Further, objective Bayesian methods are influenced by the same quality criteria that frequentist methods used, including Type I error 162 rate and power (Sellke, Bayarri, & Berger, 2001). On the other end, subjective Bayes 163 analyses include rigorously informed priors so that current knowledge can play a large role in 164 the posterior. Our current analysis splits these two; we do not utilize completely uniformed 165

(objective) priors, as we can adjust for basic knowledge of the constraints of our data type. 166 Given the usual lack of information about underlying distributions, a wider band of inclusion 167 was used for prior information. The BayesFactor package (Morey & Rouder, 2015) assists 168 greatly in the choice of prior and is especially user-friendly for applied researchers, as it 169 makes use of recommended default priors that have been chosen to be safe to assume under 170 a broad range of data and topics (Rouder, Morey, Speckman, & Province, 2012; Rouder, 171 Speckman, Sun, Morey, & Iverson, 2009). Instead of conventional F, t, and p-values, a ratio 172 of the likelihood of the alternative model to the null is report, usually BF_{10} . For instance, 173 $BF_{10} = 20$ would indicate that the effects model is favored 20 to 1 over the null model. 174 Conversely, if the BF_{10} were 0.10, the null model is favored 10 to 1 over the effects model. 175

176 Typical Procedure

177

178

179

180

181

182

183

184

185

186

The procedure behind BF comparisons requires two steps.

1) One must design two models for the data. For our purposes, the first of these models will be the null model, which states that there are no differences between means (μ ; i.e., all of our observed values X_i , regardless of which time point they were assessed at X_{ij} , arise from a normal distribution N with some mean μ and variance σ^2). The second model for these analyses is the effects model, which states that each mean (μ) is allowed to be different from the grand mean by some amount (δ ; as we now have observations being drawn from three potential normal distributions, all of which may have a different mean value, but the same variance). These can be operationalized as follows:

$$H_0: X_{ij} \sim N(\mu, \sigma^2)$$

$$H_A: X_{ij} \sim N(\mu + \delta_i, \sigma^2)$$

In designing these models, one must choose the prior distributions that are believed to
describe the data. Reasonable expectancies of where the data lie should be incorporated in
this decision based on previous research into the studied phenomena (Rouder et al., 2012).

Analyze the data given the selected priors and models. Consider the BF and use the BF_{10} as evidence of how one should update their beliefs about the models.

Based on the flexibility of the analysis, the only assumption that needs to be made is that data exists such that two competing, plausible models with different constraints may be specified.

Bayesian inference improves upon the traditional frequentist point of view by allowing 195 not only a clear interpretation of the evidence provided by the data, but also the ability to 196 speak in favor of the null hypothesis. It is important to note that while previous work has 197 indicated that p-values and BF largely agree on which hypothesis should be supported, they 198 differ in the strength of that conclusion, especially when p-values were slightly lower than α 199 (i.e., .05 to .01; Wetzels et al., 2011). However, some limitations do arise in this paradigm. 200 Bayesian analyses require the researcher to take an active role in the choice of prior 201 distributions for the phenomenon they are modeling, and this decision can take some effort 202 to fully understand; however, in the meantime, there are packages such as BayesFactor that 203 provide the researcher simple default options that can readily lend themselves to many 204 research areas with little fear of being outrageous specifications. Further, unlike NHST, 205 Bayesian analyses do not necessarily control long-run error rates, as the focus is on updating 206 current model beliefs. Another concern that many researchers have is that these analyses are necessarily sensitive to prior choice. However, research has shown that the choice of priors 208 has essentially no effect on conclusions when sufficient data has been collected as the priors 209 give way to the weight of the data (Klugkist & Hoijtink, 2007; Rouder et al., 2012) and when 210 reasonable priors are considered, data are only mildly sensitive to these (Haaf & Rouder, 211 2017). Finally, many believe Bayesian analysis to be too computationally intensive to 212

complete. However, many simple programs, packages, and tutorials exist to help ease the transition from frequentist to Bayesian analysis (JASP Team, 2017; Kruschke, 2014; Morey & Rouder, 2015).

Observation Oriented Modeling

217 History

216

James Grice argues that our problems as a science go beyond use of NHST and extend 218 into the philosophical ideas underpinning our research. Therefore, he developed a new 219 paradigm called Observation Oriented Modeling (OOM, Grice, 2011, 2014; Grice, Barrett, 220 Schlimgen, & Abramson, 2012). He reasons that by viewing psychology through the lens of 221 philosophical realism, instead of positivism, we should be able to properly and effectively 222 conduct research and analyze data. In contrast to positivism (i.e., which is solely concerned 223 with finding an effect, not with how the effect occurred), philosophical realism holds that the 224 causal structure of nature can be understood through scientific investigation. The goal is 225 then to understand the causal mechanisms that give rise to the patterns observed in a given 226 set of observations, which in here would refer to data. Switching to this philosophy allows for 227 techniques that match the daily activities of social scientists in their endeavors to unravel 228 the story of how humans operate. Using OOM, a researcher does not focus on population 229 parameters and the various assumptions underlying statistical tests (e.g., random sampling, 230 normality, homogeneity of population treatment differences, etc.).

Generally speaking, this approach can handle any type of data, including ordinal rankings and frequency counts, as all analyses are calculated in the same general fashion (see Valentine & Buchanan, 2013 for an example). This simplicity occurs because OOM works on the deep structure of the data. Through observational definition, the program separates these units into binary code. Deep structures can be arranged to form a matrix, which can

then be manipulated via matrix algebra, binary Procrustes rotation, and other operations to 237 investigate the data. The most important values from any OOM analysis are the PCC 238 (percent correct classification) values. These values represent the summation of how well an 239 individual's responses matched the stated or expected pattern or, in the case of causal 240 modeling, how many of the individual's conformed to a given cause. Complete matches are 241 the proportion of observations that match the researcher-designated pattern on all 242 dimensions. For example, in a three-level Ordinal Pattern Analysis (OPA), a person would 243 be tallied as a "complete match" if the ordinal pattern of his/her data matched the expected 244 ordinal pattern across all three levels. Imagine we have set a pattern that designates Time 1 245 < Time 2 < Time 3. For example, imagine we have data for two hypothetical individuals. Person A has values of 3, 4, and 5 at timepoints 1, 2, and 3, respectively, while person B has 247 values of 4, 5, and 2. We can see that Person A matched the pattern completely, and therefore would be counted in the PCC value. However, while person B matched the first part of our pattern (time 1 less than time 2), they did not match on the third point of our pattern (time 2 less than time 3); thus, they would not be counted in the PCC value. As the 251 PCC is simply the percentage of individuals in a sample whose responses match the expected 252 ordinal pattern perfectly, its computation is therefore not based on means or variances, but 253 on the basis of the observations themselves. The PCC value replaces all of the conventional 254 values for effect size used in statistical analyses. 255

The analysis we focus on here (OPA) does not form any type of linear or nonlinear equation or regression, but simply looks for those individuals who match the expected ordinal pattern (Grice, Craig, & Abramson, 2015). The main point of the analysis, then, is to see how many people fit the expected pattern which is based on a causal theory. If all causes are accounted for in the study and observations have been made with sufficient precision and accuracy, then 100% of the persons should fit the expected pattern; otherwise, a lower PCC value will be expected and it is up to the researcher to determine how high a PCC must be in order to support an inference to the causal mechanism.

In OOM, traditional p-values are no longer utilized (Grice, 2011). As a secondary form 264 of reference value, a chance value (c-value) is obtained, which is a type of randomization test 265 in which the researcher determines the number of randomized trials for the test (e.g. 1,000 or 266 5,000 randomized versions of actual observations). This procedure is akin to permutation 267 tests, where PCCs are computed for the randomized data to form a distribution. The 268 observed PCC is then compared to these values, and the c-value (which is an empirical 269 probability) is determined. If the randomized data sets fit the pattern as well as or better 270 than the actual data does, the c-value will be high (close to 1). Low c-values (close to 0) 271 indicate a pattern of observations that is improbable (i.e., unlikely produced by chance) 272 when compared to randomized versions of the same data. Although low c-values, like low 273 p-values, are desirable, c-values do not adhere to a strict cut-off and should be considered a 274 secondary form of confirmation for the researcher that their results are distinct.

Typical Procedure

277

278

279

280

281

282

283

284

285

OPA is analogous to repeated measures ANOVA and contains two steps.

1) Designate the expected ranked pattern: each variable as being higher, lower, or equal to the other variables. For instance, for our analyses we defined the following pattern of individual responses X_i , whereby the first time point should be less than the second time point which should be less than the third time point. This pattern can be operationalized as follows:

$$X_{i_1} < X_{i_2} < X_{i_3}$$

2) Analyze the data using OPA. Consider the PCC (the percentage of individuals matching the ordinal hypothesis) and c-values in light of the data and use your best judgment as to whether or not the data conform to the expected pattern. This analysis

only requires the assumption that the data exists such that a pattern may be designed.

As with all of these methodologies, limitations do exist. This approach is largely
concerned with patterns of responses, not with magnitudes of differences, which may be an
integral piece of information to some researchers. Unlike all approaches mentioned before, we
do not discuss the probability of some data given our hypothesis here, and instead focus on
the observed responses of the individual and how it may or may not behave as expected.
Finally, similar to the Bayesian analysis, long-run error rates are not discussed in this
methodology.

A Simulation Study

5 Simulated Data

286

294

In this study, we generated 20,000 datasets by manipulating sample size and effect size 296 for a repeated measures design with three levels. A repeated measures design was chosen as 297 it is widely used across many disciplines of psychology. These datasets were created using 298 the mytnorm package in R (Genz et al., 2017), and all code for simulations can be found at 290 https://osf.io/u9hf4/?view only=1caa9092868b4d7aadb9a83a31a979cd. Interested readers 300 can easily adapt the R code to incorporate different research designs. Likert data, ranging 301 from 1 to 7, was created by rounding mvtnorm estimates to whole numbers and truncating 302 any data points out side of the appropriate range (i.e., values < 1 were rounded to 1, and 303 values > 7 were rounded to 7). We specifically chose Likert-type data as this data type is one of the most common data types utilized by most social scientists. Additionally, we add to the literature as other simulations have chosen to use completely continuous data (i.e., simulated numbers are often precise to 10+ decimals, which is unlikely for traditional 307 sampling). The simulated data did increase in skew with this procedure from approximately 308 no skew (i.e., <0.01) to approximately 0.40 for the smallest and no effect conditions; 309

however, these values closely resembled a normal distribution with the use of mvtnorm. The 310 population means for each level were set to 2.5, 3.0, and 3.5, and pairwise effect sizes (e.g., 311 the comparison between time 1 v. time 2 and time 2 v. time 3) were manipulated by 312 adjusting the standard deviation to create negligible effects (SD = 3.39, d = 0.10), small 313 effects (SD = 3.00, d = 0.20), medium effects (SD = 0.50, d = 0.50), and large effects (SD = 0.50) 314 0.10, d = 0.80) using Cohen (1992)'s traditional guidelines for d interpretation. The smallest 315 effect size was set such that Likert style data could still be retained with the smallest 316 possible effect size. Sample size was manipulated at 10, 30, 100, 500, and 1,000 data points. 317 All combinations of the five sample sizes and four effect sizes were created, and each dataset 318 was simulated 1,000 times, totaling 20,000 datasets. 319

The advantage of using mvtnorm and set SDs for each group was the ability to
approximate the assumptions of normality by randomly generating from a multivariate
normal distribution, and homogeneity by setting equal SDs for each group. In a repeated
measures design, the assumption of sphericity was met by setting the correlations between
levels in mvtnorm to zero. By maintaining the lowest level of relationship between levels, we
additionally controlled for power and examined situations of significance given the lowest
power scenario. During the data simulation, the standard deviation of the difference scores
was examined to maintain differences greater than zero, especially for low N simulations.

328 Analyses Performed

Descriptive Statistics. Means, mean differences between levels, and the confidence intervals for each mean can be found in the complete dataset online,

https://osf.io/u9hf4/?view_only=1caa9092868b4d7aadb9a83a31a979cd. For each simulation,

we also calculated d values using the standard deviation of the difference score as the

denominator (d_z , Lakens, 2013). The MOTE library was used to calculate the non-central

confidence interval for each d value as well (Buchanan, Valentine, & Scofield, 2017;

Cumming, 2014). This data was mainly used to determine if simulations were meeting expected values overall.

Parametric NHST - Repeated Measures ANOVA. Repeated measures

ANOVA using the ezANOVA() function in the ez library was utilized with type three sum of

squares (Lawrence, 2017). This style of ANOVA is used to compare the same individuals

across multiple or all conditions in an experiment. The null hypothesis states that there are

no significant differences between population means, and the research hypothesis posits that

there are differences between some population means, but does not specify which population

means may differ, just that one or more will differ as the alternative. This test uses the Fdistribution focusing on p values.

To determine where differences may exist, post hoc dependent t-tests are normally 345 analyzed in the event of a significant F-ratio. We did not run all pairwise comparisons, 346 instead focusing on the linear trend simulated by comparing level one to two and level two to 347 three. This set of comparisons also controlled the effect size between comparisons, as 348 comparing level one to three would have doubled the effect size. However, we assumed that 349 typical researchers might compare all three pairwise combinations in practice and used a 350 Bonferroni correction across all three possible pairwise combinations to calculate p values for 351 post hoc tests. Therefore, while we only discuss the two comparisons, we utilized the more 352 stringent cutoff of the Bonferroni correction as we believe this procedure would be how the 353 majority of researchers would handle the data. Interested readers can find all three 354 comparison values in the complete dataset online. Following traditional usage, a p-value of less than .05 was binned as significant, whereas p-values ranging from .10 to .05 were binned as marginally significant. Any p-values larger than .10 were binned as non-significant. A 357 second set of p-value comparisons was calculated given Benjamin et al. (2018)'s suggestion 358 to change α criterion to less than .005. Any p-value less than .005 was binned as significant, 359 while data ranging from .005 to .10 was marginal or suggestive, and p > .10 was 360

non-significant.

Bayesian Analysis: Bayes Factor. We compared a null model with one grand 362 mean for all three levels to an effects model wherein means were allowed to differ using the 363 BayesFactor package (Morey & Rouder, 2015). The default in this package is a Jeffreys prior 364 with a fixed rscale (0.5) and random rscale (1.0). BF were calculated, and follow up t-test BFs were computed for the same two comparisons as in the previous models using default 366 priors from the BayesFactor package (e.g., Jeffreys prior for population variance, Cauchy prior for standardized effect size). To compare Bayesian results to other statistical methods, we used recommendations from Kass and Raftery (1995) to bin results into weak evidence (BFs < 3), positive evidence (e.g., akin to marginal p-values, BFs = 3-20), and strong 370 evidence (BFs > 20). We must stress here that BF interpretation should focus on 371 understanding the odds of model ratios, not necessarily the presence or absence of an effect. 372 However, given that we wanted to compare the conclusions one would reach given this data 373 in a Bayesian paradigm to that of a frequentist paradigm, these bins are used as a convenient 374 comparison to the frequentist procedures using set criteria for interpretation (Morey, 2015). 375 Should any reader become curious how a different set of binning values affect our analyses, 376 all code and data are at their disposal at 377 https://osf.io/u9hf4/?view only=1caa9092868b4d7aadb9a83a31a979cd, and this manuscript 378 was written with the papaja package allowing one to view the code inline with this text 370 (Aust & Barth, 2017). 380

OOM: Ordinal Pattern Analysis. An R script of the Ordinal Pattern Analysis
from Grice et al. (2015)'s OOM program was provided from Sauer and Luebke (2016). We
set the expected ranked pattern as level one less than level two less than level three. Once
this pattern was defined, we then analyzed the data to see if each individual's set of
observations matched this expected ordinal pattern. PCC values were generated, and
c-values were computed by randomizing the data 1,000 times. Solely for purposes of

comparison, we used the following significance coding schema: significant studies had a high 387 PCC value (.50 < PCC < 1.00) and a low c-value (c < .05), marginal studies had a high 388 PCC value and a moderate c-value (.05 < c < .10), and non-significant studies had low PCC 389 values (PCC < .50), regardless of their c-values. Again, we must stress that this paradigm 390 eschews binning estimates and that our use of bins was a) discussed and decided upon before 391 data analysis, and b) created only for the purposes of comparing this new methodologies 392 possible conclusions to that of a frequentist framework. We welcome interested readers to 393 explore the data more, defining their own bins and viewing the affects, by viewing and 394 editing our code online. 395

Results

77 Percent of Estimates

For all simulations, we first binned the estimates into significant, marginal, and 398 non-significant effect categories as described in the Analyses Performed section above. Next, 399 we calculated the percentage of these analyses that would be classified into each of these 400 categories, separated about by statistical analysis, sample size, and effect size. These 401 estimates were binned across both the overall and follow up post hoc tests, and the combined 402 data are presented for this analysis. Since all three categories of binning total to 100%, we 403 present only the significant and non-significant results. Significant critical omnibus estimates 404 are presented in Figure 1. All figures discussed in this manuscript may be viewed as interactive graphics on our OSF page through a provided Shiny app. In Figures with sample size on the axes, we log transformed N to allow for visual distinction between sample sizes, 407 as smaller N values were compressed when using the N=10 to 1000 on the axis. Both N 408 and $\log(N)$ can be found in the Shiny app, along with the ability to zoom in to specific 409 ranges of sample size. 410

For negligible effects at p < .05 (solid lines), we found that NSHT analyses showed a 411 predictable Type I error bias, in that they detected significant estimates with extremely 412 small d values as sample size increased. Binned BF values showed a similar pattern, but 413 were more conservative with less percent significant estimates. OOM analyses were the most 414 conservative, essentially never detecting an estimate in the negligible effect simulations. 415 Small effect sizes showed the same pattern for NHST, BF, and OOM results, with the 416 proportion of significant estimates increasing more rapidly and asymptoting at a smaller 417 sample size than negligible effects. At medium effect sizes, NHST analyses nearly always 418 detected significant estimates, while BF and OOM analyses would have been considered 419 significant around 75% of the time. Interestingly, with large effect sizes, OOM analyses 420 mirrored NHST by always detecting estimates, and BF analyses were generally more 421 conservative except at the largest sample size. Figure 1's dashed lines indicate the results if values were binned at p < .005, and the differences between these results were very subtle. 423 Lowering α reduced the number of significant estimates at small N values for all four effect sizes, with more pronounced differences at negligible and small effect sizes. However, the 425 graphs converged to the same conclusion that large enough sample sizes could produce 426 significant results at negligible and small effect sizes.

Figure 2 portrays the results for non-significant binned simulations, which were the 428 same for both α criterion. Across all effect sizes, BF and NHST showed similar results, 429 where non-significant estimates were detected at lower sample sizes for negligible and small 430 effect size simulations. At medium and large effect sizes, almost all estimates would have 431 been considered significant, therefore, detection rates for non-significant estimates were 432 around zero. OOM displayed a conservative set of findings, showing nearly 100% 433 non-significant estimates at negligible and small effect sizes (mirroring results from Figure 1). 434 At medium effect sizes, approximately a quarter of estimates were non-significant, 435 illustrating the conservative nature of OOM interpretations. 436

Figure 3 depicts the relationship between the effect size of time 1 minus time 2 and the 437 corresponding PCC values. These metrics appear to represent different concepts where effect 438 size measures the magnitude of the difference between two data points while PCC disregards 439 magnitude and represents the proportion of the sample following the given ordinal pattern 440 across all three time points. Given these differences, it is interesting how well these two 441 measures converge together. As sample size increases, estimates for both d and PCC become 442 more precise (i.e., smaller range, closer to the simulated effect size). We believe that PCC 443 offers researchers the ability not only to confirm that their effect size is reasonable, but also to better understand the pattern their data are following, especially if an observed effect size 445 contradicts previous literature. For example, let us assume there is previous literature that 446 states that a small positive effect exists, such that responses should increase from time 1 to 447 time 2. Under conditions of a true small effect (d=-0.20) and sample size of 30, our graph shows us that it is possible to obtain a positive medium effect size (d = 0.50; indicating the time 1 is more extreme than time 2). Upon finding these contradicting results, the researcher could further seek to understand the pattern their data are following by computing the PCC 451 value for the experiment. The PCC value for this example would be above .50, indicating 452 that, in over half of respondents the values for time 1 are less than time 2 (in turn less than 453 time 3, as it measures the entire pattern), even though magnitude of change suggests that 454 time 1 is larger than time 2. This gives the researcher a richer piece of information, which 455 can help to describe their results in a more nuanced fashion. 456

457 Percent Agreement

A goal of this project was to expand the toolbox of options for researchers to determine
what evidence supports their hypotheses by examining multiple methodologies. We
calculated the percent of time that all analyses agreed across overall and *post hoc* comparison
estimates. Figure 4 illustrates the pattern of 100% agreement on effects for critical omnibus

tests only at each sample size and effect size. Figure 5 portrays the results for *post hoc* tests, which only uses NHST and Bayes Factor analyses, as OOM does not have a *post hoc* test (i.e., the test is a pattern analysis that presupposes the expected direction of *post hoc* tests).

When effect sizes were negligible and for small effects, agreement was best across small 465 samples and decreased across sample size, as NHST was overly biased to report significant 466 estimates and OOM and BF were less likely to do so. For medium and large effect sizes, 467 50-75% agreement was found, usually regardless of sample size. Additionally, we found that 468 for negligible, small, and medium effects, agreement for post hoc tests was higher than 460 agreement for overall comparisons. The post hoc comparisons for levels 1 to 2 and levels 2 to 470 3 were less likely to be binned as significant across negligible and small effects, so the 471 agreement levels were higher for these individual comparisons due to non-significant follow 472 up tests. The critical omnibus test was more likely to be significant due to the inclusion of 473 effect of comparisons between level 1 and 3, which were double the effect size. However, 474 these post hoc comparisons do not include the conservative significant binning from OOM, 475 which decreased critical omnibus 100% agreement seen in Figure 4. Again, the differences between p < .05 and p < .005 were minimal. Complete tables of percentages of binning across critical omnibus and post hoc tests, along with agreement percentages broken down by bins can be found at https://osf.io/u9hf4/?view only=1caa9092868b4d7aadb9a83a31a979cd.

480 Criterion Comparison

As the relationship between BF and p-values is already well documented, we will not discuss them here beyond stating that we found the expected pattern shown in previous work (Rouder et al., 2012), and that individuals who wish to view this comparison, as well as all the other comparisons discussed here should visit our interactive Shiny application at our OSF page. Of interest was the comparison of OOM indices to traditional NHST and Bayesian indices. First, in Figure 6, PCC values are plotted against log BF values and

p-values. The log of BF was taken to include all values on a viewable axis, and all infinity values were windsorized to the next highest point. Increasing sample size is shown by increasing point size and lighter colors. Additionally, since OOM values are a combination of PCC and c-values, c-values below .05 are shown as Xs instead of dots. Therefore, all values PCC >= .50 that are also denoted as Xs would be considered significant in this example. The provided Shiny application uses color to distinguish sample size differences, as well as includes options to create each combination effect size and criterion individually. Only two graphs are provided here to save space.

In Figure 6, the left hand column portrays the relationship between log BF values and PCC values in negligible and medium effect sizes. With negligible effect sizes, we found large variability in PCC values across a small span of BF values while sample sizes remained low, 497 but as N increased, we saw that the range of PCC values narrowed considerably with 498 increasing BF values. Therefore, as sample size increased, the PCC values constricted, while 499 BF values expanded. A similar pattern appeared when viewing the medium sample size 500 graph, as again PCC values became less variable with increased sample size, and BF tended 501 to increase both in variability and in value as the sample size grew. Here, we can see a 502 benefit of PCC, along with c-values, as increasing sample size portrayed more precision in 503 PCC, instead of the increased variability found in BF. 504

It is also important to note that within the negligible effects graph, while many of
these PCC values reached high values, that these values did not denote patterns that would
necessarily be seen as unique. c-values were a secondary measure of evaluation that
eliminated a number of these matches from being considered meaningful. A large majority of
points with larger sample sizes on the figure included low chance values, however, the PCC
values for these simulations were lower than a meaningful percent used for cutoff criterion.
This two-step process helped to weed out effects that were negligible, especially at larger
sample sizes.

Additionally, we compared p-values and PCC values, which are illustrated on the right 513 hand side of Figure 6. Again, PCC values showed far more variability with small sample 514 sizes, and the p-values associated with these smaller sample sizes were also quite variable. 515 Importantly, even when an effect was negligible, PCC values become less variable with 516 increasing sample size. PCC values also indicated that there was little evidence of the 517 hypothesized pattern by shifting toward zero. p-values decreased in variability at high 518 sample sizes and shifted toward minuscule values, thus, pointing toward rejecting the null 519 hypothesis. With medium effect sizes, both p-values and PCC values were variable at small 520 sample sizes. At larger sample sizes, p-values decreased towards floor effects (i.e., closer to 521 zero), while PCC values simply narrowed in range shifting slight above .50. The benefit of 522 multiple criteria evaluation here was clear, as p-values increasingly indicated significance as 523 sample size increased, PCC values were not effected in this way and thus presented a more stable picture of the presence of an effect. While multiple criteria may not completely reduce the interpretation of false positives in the literature, the relationship between these values illustrated that multiple indices can provided a clearer picture of the evidentiary value 527 available in a study. 528

Limitations

Within any study a number of limitations exist. The largest limitation of our study is
that we chose to focus on a simple three level repeated measures ANOVA design. The
benefit to this focus is the simplicity of understanding the relationship between analyses,
while also using a well understood NHST procedure. However, is possible that these same
relationships may or may not exist in alternative design contexts. Additionally, our choices
for classification of significant effects for *p*-values, BF, PCC, and *c*-values was based on what
we believe a reasonable researcher may designate; however, these classifications may vary in
the real world. We provide open access to our simulations and code so that an interested

party can tinker with these choices. We believe the global conclusions would likely be similar across changes, however, the specific percentages and patterns would likely differ. Finally, due to the specification of our simulation we did not violate any statistical assumptions. It is possible that the violation of these assumptions may cause changes in the relationships we see here.

543 Discussion

This manuscript was designed to showcase two alternative paradigms to NHST 544 researchers and to compare the conclusions these alternative methodologies might make in a 545 given data environment to those NHST would make. We believe that the awareness of 546 multiple methodologies might assist in strengthening our conclusions and improving 547 reproducibility by giving researchers the ability to identify an optimal method given the 548 question at hand. Further, we believe that should a researcher utilize multiple methodologies 549 (e.g., analyzing and reporting both a NHST p-value as well as an OOM PCC value) that 550 these estimates in tandem can help readers to weight these various forms of evidence and 551 arrive at a more robust conclusion. We found that changing the threshold at which p-values 552 are deemed significant had little to no effect on conclusions, especially at large sample sizes, 553 regardless of effect size. This finding is notable as the article by Benjamin et al. (2018) states that an increase in sample size is likely to decrease false positives "by factors greater than two" (p. 10), and work by Pericchi and Pereira (2016) state that an adaptive level of 556 significance would be beneficial in these circumstances—neither of which are not supported 557 by our simulations. Our science will not grow by moving the significance line in the sand, as 558 this line has already been shown to have "no ontological basis" (Rosnow & Rosenthal, 1989, 550 p. 1277). 560

Instead, we need to embrace the multitude of perspectives available to us and to begin to employ these diverse approaches. While NHST can still serve us well when properly

utilized, it is important for researchers to understand that different methods seek to answer 563 different questions, and that we need to ensure that we are using the right method to answer 564 a given question. When evaluating evidence in order to answer these questions we must be 565 warv of looking for significant differences and focus instead on finding meaningful differences. 566 By combining these approaches we may be better able to qualify the strength of our evidence 567 and discuss a more nuanced version of our data. Additionally, while all of these methods 568 have drawbacks, when used in combination these methods can begin to overcome many of 569 these limitations. For instance, given a large sample size, we would expect BF values to be 570 very large and p-values to be very small, both indicating that the null model/hypothesis 571 should not be supported. However, if we also have a PCC value of .30, we may decide that it 572 is possible that this effect is very small and possibly negligible. This multifaceted approach 573 can help to curb our enthusiasm over small or negligible "significant" effects that may not be practically meaningful and possibly may not replicate. Regardless if analyses agree or 575 disagree on the presence of an effect, a researcher can investigate the direction and size of the effect, the proportion of data that agrees or disagrees with the direction of the effect, and 577 discuss conclusions accordingly. Each methodology behaves slightly differently in given data 578 environments, which might begin to highlight meaningful differences when discussed together.

Some may contest that all of these analyses are capable of being hacked, like p-values, 580 through researcher degrees of freedom, choice of priors, or pattern choice, among other 581 actions (Simmons et al., 2011). Transparency throughout the research process is key to 582 eliminating these issues, as α changes may only encourage bad research practices with the 583 current incentive structure on publishing. Although we have the capability to share research across the world, research often still occurs behind closed doors. The Open Science Framework grants insight into research processes, allowing researchers to share their methodologies, code, design, and other important components of their projects. In addition 587 to posting materials for projects, pre-registration of hypotheses and methodology will be an 588 important facet in scientific accountability. Further, with increased transparency editors and 589

other researchers can weigh the evidence presented according to their own beliefs.

Our key suggestion in this project is the redefinition of evidentiary value. The current 591 focus on p-values has shown to be problematic, as many of the studies from the Open 592 Science Collaboration (2015) do not replicate at p < .05 or p < .005 (Lakens et al., 2018). 593 With the change in transparency mentioned above, publishing research with solid research designs and statistics, regardless of p-values, will allow for a broader range of evidence to 595 become available. Publishing null findings is critical in replication and extension for 596 discovering the limits and settings necessary for phenomena. Registered replications and reports will allow studies to be accepted prior to results being known, thus allowing researchers to focus on experimental design and hypotheses appriori instead of p-values post 599 hoc. Reports should describe multiple indicators of evidence, such as effect sizes, confidence 600 intervals, power analyses, Bayes Factors, and other descriptive statistics (Finkel, Eastwick, & 601 Reis, 2015; Nosek & Lakens, 2014; van't Veer & Giner-Sorolla, 2016). 602

A misunderstanding of statistical power still plagues psychological sciences (Bakker, 603 Hartgerink, Wicherts, & van der Maas, 2016), and the effect of sample size, especially small 604 ones, was shown here by comparing the criterion available in these analyses. Often, 605 individual research labs may not have the means to adequately power a proposed study. 606 Multilab studies and collaboration with other scientists is fundamental to alleviating these 607 issues, while encouraging interdisciplinary science. Collaboration increases our statistical 608 abilities, as every researcher cannot be expected to be proficient in all methods and analyses, 609 but teams of researchers can be assembled to cover a wider range of statistical skills to provide adequate estimates of evidence in their reports. We understand that there may be resistance to the implementation of multiple methodologies as these new methodologies take 612 time and effort to learn. However, through the use of free programs (JASP, R, OOM, Shiny) 613 and tutorials (YouTube, Coursera, http://www.statstools.com), we believe all researchers are 614 capable of learning these analyses. We believe that through the expansion of our analytical 615

 k_{0} knowledge and application of these new methodologies, we can begin to attenuate some of

 $_{617}$ the strain currently placed on psychological science and to increase the strength of evidence

618 in our discipline.

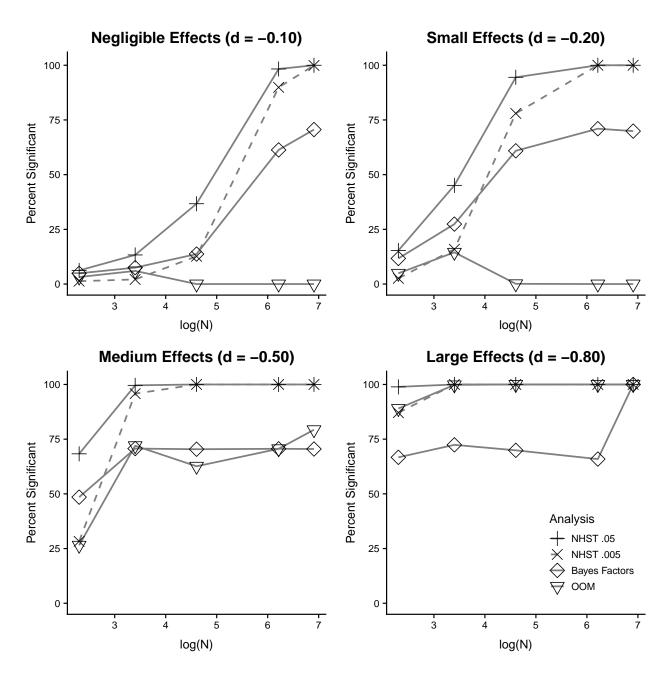

Figure 1. For NHST analyses only, percent of significant estimates at p < .05 (solid) and p < .005 (dashed) for each analysis given effect size and sample size.

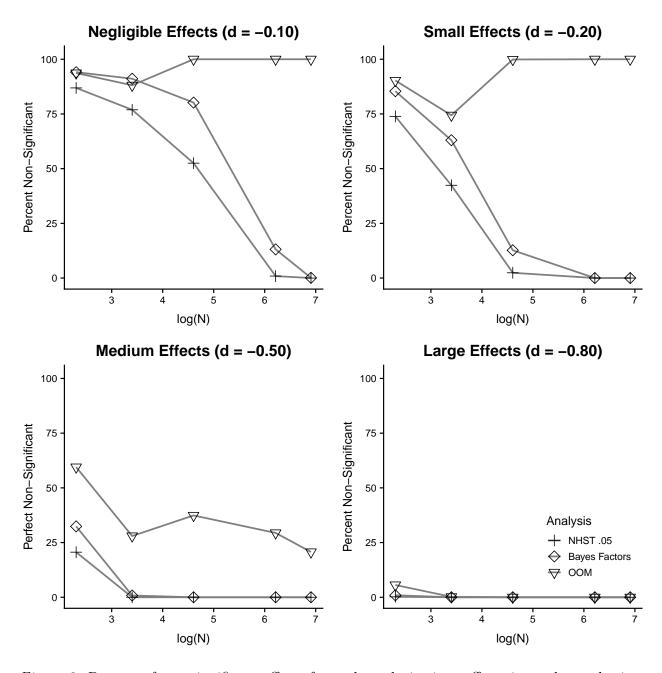

Figure 2. Percent of non-significant effects for each analysis given effect size and sample size.

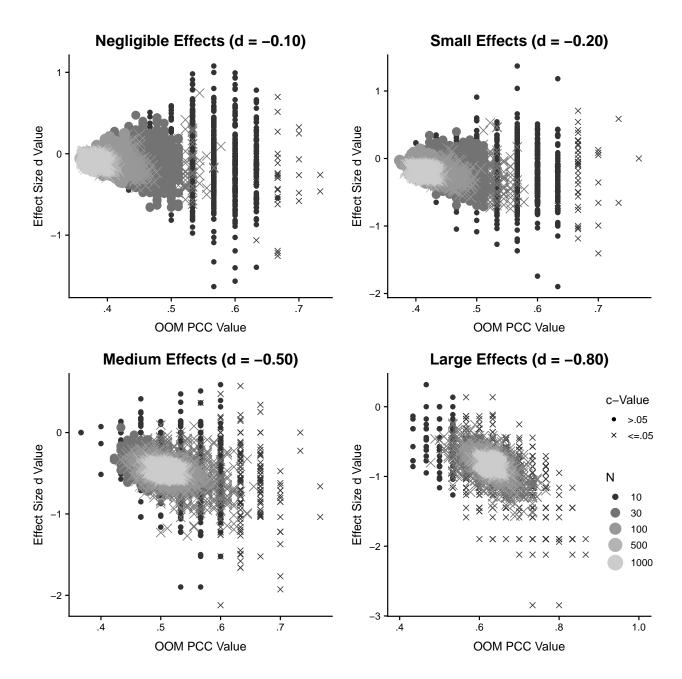

Figure 3. PCC and c-values plotted against observed effect size (d-values) given effect size and sample size conditions. Xs indicate simulations with c-values < .05, which were binned as significant if they were found in conjunction with PCC values over .50. Point size and color indicates sample size wherein larger samples are lighter colors. Please note that the key for the entire set of graphics is in the bottom right hand corner.

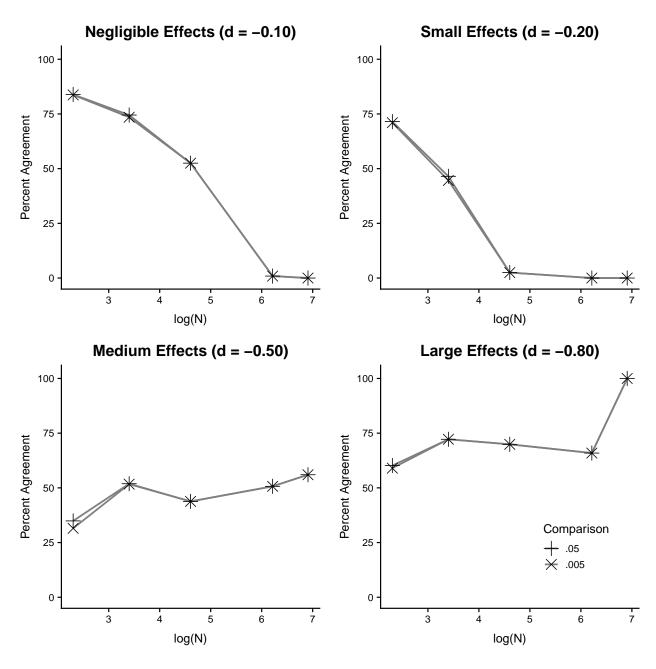

Figure 4. Percent of agreement across all analyses given effect size and sample size for omnnibus tests.

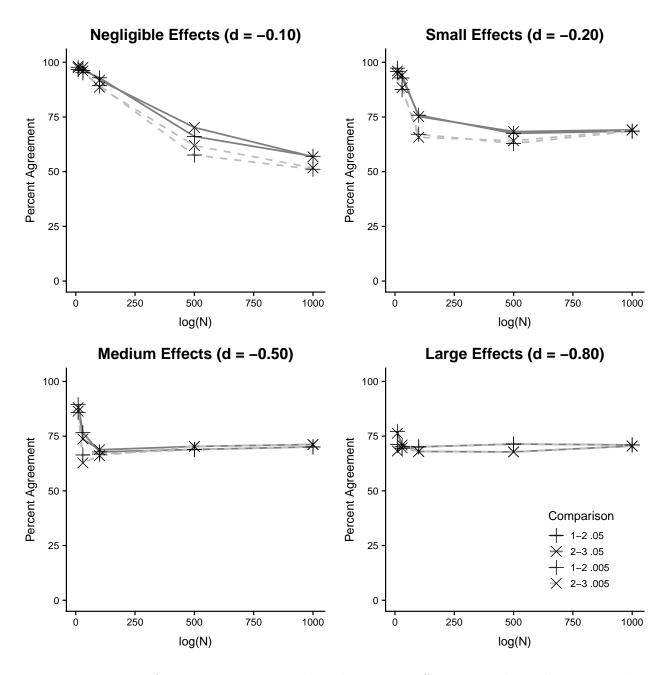

Figure 5. Percent of agreement across each analysis given effect size and sample size posthoc tests with p < .05 (solid) and p < .005 (dashed). Note that this graph only compares the NHST and BF conclusions.

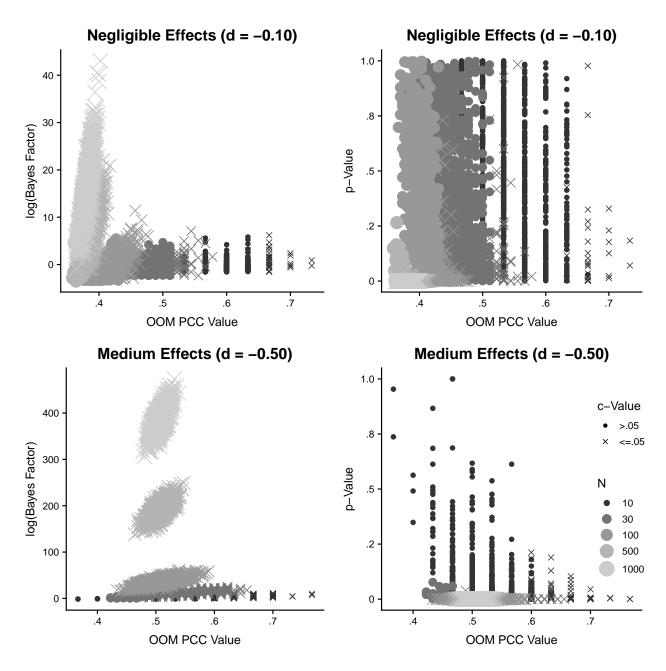

Figure 6. PCC and c-values plotted against p and BF values for negligible and medium effect size conditions. Xs indicate simulations with c-values < .05,which were binned as significant if they were found in conjunction with PCC values over .50. Point size and color indicates sample size wherein larger samples are lighter colors. Please note that the key for the entire set of graphics is in the bottom right hand corner.
