Beyond p-values: Utilizing Multiple Methods to Evaluate Evidence

Abstract 2

Null hypothesis significance testing (NSHT) is cited as a threat to validity and

reproducibility. While many individuals suggest we focus on altering the p-value at which we

deem an effect significant, we believe this suggestion is short-sighted. Alternative procedures

(i.e., Bayesian analyses and Observation Oriented Modeling; OOM) can be more powerful

and meaningful to our discipline. However, these methodologies are less frequently utilized

and are rarely discussed in combination with NHST. Herein, we discuss three methodologies

(NHST, Bayesian Model comparison, and OOM), then compare the possible interpretations

of three analyses (ANOVA, Bayes Factor, and an Ordinal Pattern Analysis) in various data 10

environments using a frequentist simulation study. We find that changing significance 11

thresholds has little effect on conclusions. We find that evaluating multiple estimates as 12

evidence of an effect allows for more robust and nuanced reports of findings. These findings 13

suggest the need to redefine evidentiary value and reporting practices. 14

Modeling, evidence

Beyond p-values: Utilizing Multiple Methods to Evaluate Evidence

17

Recent events in psychological science have prompted concerns within the discipline 18 regarding research practices and ultimately the validity and reproducibility of published 19 reports (Etz & Vandekerckhove, 2016; Lindsay, 2015; Open Science Collaboration, 2015; van 20 Elk et al., 2015). One often discussed matter is over-reliance, abuse, and potential hacking of 21 p-values produced by frequentist null hypothesis significance testing (NHST), as well as 22 misinterpretations of NHST results (Gigerenzer, 2004; Ioannidis, 2005; Simmons, Nelson, & Simonsohn, 2011). We agree with these concerns and believe that many before us have voiced sound, generally accepted opinions on potential remedies, such as an increased focus on effect sizes (Cumming, 2008; Lakens, 2013; Maxwell, Lau, & Howard, 2015; Nosek, Spies, & Motyl, 2012). However, other suggestions have been met with less enthusiasm, including a recent article by Benjamin et al. (2018) advocating that researchers should begin thinking only of p-values less than .005 as "statistically significant", thus changing α levels to control 29 Type I error rates. Additionally, Pericchi and Pereira (2016) promote the use of fluctuating α levels as a function of sample size to assist with these errors. We argue it is not the 31 threshold, or critical p, that needs to be rethought when seeking evidence, but rather if a 32 p-value should be utilized at all, and, if so, what that p-value can tell you in relation to other 33 indicators. While NHST and p-values may have merit, researchers have a wealth of other statistical tools available to them. We believe that improvements may be made to the 35 sciences as a whole when individuals become aware of the tools available to them and how these methods may be used, either alone or in combination, to strengthen understanding and conclusions. These sentiments have been shared by the American Statistical Association who recently held a conference focusing on going beyond NHST, expanding their previous stance p-values (Wasserstein & Lazar, 2016).

Therefore, we undertook this project to show researchers how two alternative paradigms compare to NHST in terms of their methodological design, statistical

interpretations, and comparative robustness. Herein, we will discuss the following methodologies: NHST, Bayes Factor comparisons, and Observation Oriented Modeling. The three approaches will be compared via simulated data using a three timepoint repeated 45 measures design with a Likert-type scale as the outcome variable. One goal of this study is to introduce social scientists to Observation Oriented Modeling (OOM), as it is a relatively 47 new paradigm that is readily interpretable and, as we will show, useful in these contexts. Additionally, we aim to discuss the conclusions these three methods reach given the same data, and to compare how often these methodologies agree within different data environments (i.e., given varying sample sizes and effect sizes). We hope that by discussing 51 these methodologies in terms of a simple statistical analysis researchers will be able to easily compare and contrast methodologies. For this discussion, it is important to understand their historical background, procedural steps, and limitations, which are outlined below. After this discussion, we describe a simulation study comparing methodologies and α criteria, and end with potential implications for researchers.

Null Hypothesis Significance Testing

58 History

57

Many attribute the frequentist NHST procedure to Ronald A. Fisher (Fisher, 1932).

However, Fisher's ideas are a far cry from the NHST procedure implemented today. Fisher believed in creating one "null" hypothesis, which he described as a hypothesis to be "nullified", or shown incorrect, not as a zero-difference hypothesis (Lehmann, 2011). He also believed that the use of any omnibus level of significance showed a "lack of statistical thinking" (Gigerenzer, Krauss, & Vitouch, 2004). He instead believed we should report the exact significance value of a test and let others make their own decision about the claims, which is more in line with the typical reporting recommendations provided by the American Psychological Association (American Psychological Association, 2010). Fisher spoke of this

work to William Gosset, the man who created the Student's *t*-test and contributed work on the correlation coefficient (Lehmann, 2011). Gosset in turn discussed the idea of an alternative hypothesis, a piece not included in Fisher's procedure, with decision theorist Egon Pearson.

From this discussion, Egon Pearson and Jerzy Neyman created Neyman-Pearson 72 decision theory. This theory consists of two hypotheses (i.e., null and alternative) and a 73 binary decision criteria (i.e., significant or not, Lehmann, 1993). However, this procedure created the possibility of researcher decision errors (Dienes, 2008). A researcher may falsely 75 reject the null hypothesis (Type I error, α) or falsely fail to reject the null (Type II error, β). 76 α levels set the binary decision criteria, which are used as the critical p-value for hypothesis 77 testing (i.e., p < .05), and are thus seen as evidence to reject the null hypothesis. β and 78 power are inherently linked (Power = $1-\beta$), so as the likelihood of finding a true effect 79 increases beta decreases (Maxwell & Delaney, 2004). Although α values can be chosen to be quite small, and methods (such as decreasing error variance or using a one-tailed test in contrast to a two-tailed test) can decrease β values as well, a researcher can never know if they have made the correct decision, or a decision error. Thus, Neyman and Pearson clearly state that a hypothesis should not be blindly supported based solely on the estimates of one statistical test, and that replication and reproduction of results are imperative. The recent work of the Open Science Collaboration (2015) has also highlighted the need for replication studies and interpretation of results in an appropriate context. Additionally, Neyman and Pearson emphasized that use of set α s and β s is illogical and sought instead for researchers to adjust their analysis to the needs of the particular task at hand (Gigerenzer, 2004). 89

90 Typical NHST Procedure

Neither Fisher's hypothesis testing, nor Neyman-Pearson decision theory quite match the NSHT procedure as it is taught and applied today. Psychologists have largely adopted

an amalgamation of the two approaches. Here, we attempt to outline what we believe is the most appropriate way to carry out the traditional NHST procedure in the context of a repeated measures ANOVA with three levels, although we note that this set of steps is not necessarily how researchers carry out the procedure in practice:

1) Create two hypotheses, one to be "nullified" and one "alternative" hypothesis. Within this repeated measures framework, most researchers would define a null hypothesis (H_0) that indicates of all three time point population means are equal. The alternative hypothesis (H_A) would then be that not all of the population means are equal. These can be operationalized in our example data as follows (note that for H_A , we use a common short hand to denote the model wherein any difference is hypothesized across the possible combinations of [in]equality):

$$H_0: \mu_1 = \mu_2 = \mu_3$$

$$H_A: \mu_1 \neq \mu_2 \neq \mu_3$$

- 2) Select an α level that is appropriate given the context of your research, your analysis plan, and your research question, and do not blindly adopt an omnibus critical p-value (Lakens et al., 2018; Lehmann, 2011). Again, we reiterate that α justification and selection is not necessarily how all researchers approach these tests.
- 3) Compute your given analysis and identify the corresponding p-value. If your p-value is less than the chosen α , reject the null hypothesis and state that there appear to be differences between some of your population means; however, if your p-value is greater than or equal to the value selected, do not reject the null hypothesis, and state that a difference between the population means could not be supported.
- While the NHST procedure itself gives us testable models, the specific analysis used to test these models here, the repeated measures ANOVA with three levels, requires some

additional assumptions that must be met before an analysis is begun (Tabachnick & Fidell, 2012). Data need to have no outlying or influential observations. Data must have a normal sampling distribution, be linearly related, and have independent errors. Depending on the statistical test, data must also be checked for equal variances, sphericity, and additivity. These assumptions can be checked and, if necessary, corrected for; however, violations of these assumptions can lead to inaccurate decisions and attenuated power. Further, with many analysis programs, data are required to have no missing values.

While this approach is widely used, there are many limitations associated with it. 122 First, this method can be sensitive to violations of the stated assumptions, and especially, if 123 the sample size is not large enough to create a normal sampling distribution (Tabachnick & 124 Fidell, 2012). Even if assumptions are met, or nonparametric tests are implemented (e.g., for 125 situations where a normal distribution assumption cannot be met), this methodology does 126 not allow a researcher to state anything about the absence of an effect (i.e., no true 127 differences). Through traditional NHST, one can only discuss evidence regarding the 128 alternative hypothesis; one can never support the null hypothesis through this procedure. Given the recent findings regarding reproducibility, showing support for the absence of an effect can be even more crucial than showing support for the presence of an effect (Bakker, 131 van Dijk, & Wicherts, 2012; Lakens, 2017). 132

Bayes Factors

34 History

133

Thomas Bayes was a statistician and Presbyterian minister whose works are still influential today (Bellhouse, 2004). Bayes' theorem solved the inverse probability problem, namely that through the frequentist approach, one can only know the probability of data existing given a hypothesis being true, never the probability of a hypothesis being true given

that the data exist (Dienes, 2008). Bayes' theorem allows one to calculate the probability of 139 a hypothesis given some data (posterior belief) by using how probable one believes the 140 hypothesis to be before data was collected (prior belief) and how probable one believes the 141 data to be given one's hypothesis (likelihood). Thus, with his theorem, researchers are able 142 to update (through the use of the likelihood) our initial beliefs (our prior) given some data 143 (Gelman, Carlin, Stern, & Rubin, 2013). Pierre-Simon Laplace pioneered Bayesianism and 144 advocated for a broader interpretation of this theorem (De Laplace, 1774). The use of 145 Bayesian statistics has been suggested as an NHST alternative (Dienes, 2014; Wagenmakers, 2007), but this approach has largely been undervalued in favor of frequentist methods as, 147 until recently, Bayesian analysis required considerable computational effort. However, today 148 we possess the technology necessary to efficiently conduct Bayesian analyses. While open 149 source software, such as R and JASP, require minimal learning to be able to effectively operate (Morey & Rouder, 2015), researchers will need to invest more effort to understand 151 the focus and interpretation of Bayes Factor (BF) comparisons as they differ from traditional 152 NHST. 153

The Bayesian framework can be viewed as a continuum, with objective Bayesian 154 analyses on one end, and subjective Bayesian analyses on the other (Press, 2002). While this 155 topic could lend itself to its own manuscript, here we will simply summarize the two 156 endpoints, and discuss where our analysis may be perceived to fall on the line. Objective 157 Bayesian analysis is closest to frequentist theory, as the aim is to minimize the influence of 158 priors through the use of non-informative priors (such as Jefferys priors that are designed to 159 be invariant under reparameterization Datta & Ghosh, 1996); thus, the data are allowed to maximally effect the posterior distribution. Further, objective Bayesian methods are influenced by the same quality criteria that frequentist methods used, including Type I error 162 rate and power (Sellke, Bayarri, & Berger, 2001). On the other end, subjective Bayes 163 analyses include rigorously informed priors so that current knowledge can play a large role in 164 the posterior. Our current analysis splits these two; we do not utilize completely uniformed 165

(objective) priors, as we can adjust for basic knowledge of the constraints of our data type. 166 Given the usual lack of information about underlying distributions, a wider band of inclusion 167 was used for prior information. The BayesFactor package (Morey & Rouder, 2015) assists 168 greatly in the choice of prior and is especially user-friendly for applied researchers, as it 169 makes use of recommended default priors that have been chosen to be safe to assume under 170 a broad range of data and topics (Rouder, Morey, Speckman, & Province, 2012; Rouder, 171 Speckman, Sun, Morey, & Iverson, 2009). Instead of conventional F, t, and p-values, a ratio 172 of the likelihood of the alternative model to the null is report, usually BF_{10} . For instance, 173 $BF_{10} = 20$ would indicate that the effects model is favored 20 to 1 over the null model. 174 Conversely, if the BF_{10} were 0.10, the null model is favored 10 to 1 over the effects model. 175

176 Typical Procedure

177

178

179

180

181

182

183

184

185

186

The procedure behind BF comparisons requires two steps.

1) One must design two models for the data. For our purposes, the first of these models will be the null model, which states that there are no differences between means (μ ; i.e., all of our observed values X_i , regardless of which time point they were assessed at X_{ij} , arise from a normal distribution N with some mean μ and variance σ^2). The second model for these analyses is the effects model, which states that each mean (μ) is allowed to be different from the grand mean by some amount (δ ; as we now have observations being drawn from three potential normal distributions, all of which may have a different mean value, but the same variance). These can be operationalized as follows:

$$H_0: X_{ij} \sim N(\mu, \sigma^2)$$

$$H_A: X_{ij} \sim N(\mu + \delta_i, \sigma^2)$$

In designing these models, one must choose the prior distributions that are believed to
describe the data. Reasonable expectancies of where the data lie should be incorporated in
this decision based on previous research into the studied phenomena (Rouder et al., 2012).

Analyze the data given the selected priors and models. Consider the BF and use the BF_{10} as evidence of how one should update their beliefs about the models.

Based on the flexibility of the analysis, the only assumption that needs to be made is that data exists such that two competing, plausible models with different constraints may be specified.

Bayesian inference improves upon the traditional frequentist point of view by allowing 195 not only a clear interpretation of the evidence provided by the data, but also the ability to 196 speak in favor of the null hypothesis. It is important to note that while previous work has 197 indicated that p-values and BF largely agree on which hypothesis should be supported, they 198 differ in the strength of that conclusion, especially when p-values were slightly lower than α 199 (i.e., .05 to .01; Wetzels et al., 2011). However, some limitations do arise in this paradigm. 200 Bayesian analyses require the researcher to take an active role in the choice of prior 201 distributions for the phenomenon they are modeling, and this decision can take some effort 202 to fully understand; however, in the meantime, there are packages such as BayesFactor that 203 provide the researcher simple default options that can readily lend themselves to many 204 research areas with little fear of being outrageous specifications. Further, unlike NHST, 205 Bayesian analyses do not necessarily control long-run error rates, as the focus is on updating 206 current model beliefs. Another concern that many researchers have is that these analyses are necessarily sensitive to prior choice. However, research has shown that the choice of priors 208 has essentially no effect on conclusions when sufficient data has been collected as the priors 209 give way to the weight of the data (Klugkist & Hoijtink, 2007; Rouder et al., 2012) and when 210 reasonable priors are considered, data are only mildly sensitive to these (Haaf & Rouder, 211 2017). Finally, many believe Bayesian analysis to be too computationally intensive to 212

complete. However, many simple programs, packages, and tutorials exist to help ease the transition from frequentist to Bayesian analysis (JASP Team, 2017; Kruschke, 2014; Morey & Rouder, 2015).

Observation Oriented Modeling

217 History

216

James Grice argues that our problems as a science go beyond use of NHST and extend 218 into the philosophical ideas underpinning our research. Therefore, he developed a new 219 paradigm called Observation Oriented Modeling (OOM, Grice, 2011, 2014; Grice, Barrett, 220 Schlimgen, & Abramson, 2012). He reasons that by viewing psychology through the lens of 221 philosophical realism, instead of positivism, we should be able to properly and effectively 222 conduct research and analyze data. In contrast to positivism (i.e., which is solely concerned 223 with finding an effect, not with how the effect occurred), philosophical realism holds that the 224 causal structure of nature can be understood through scientific investigation. The goal is 225 then to understand the causal mechanisms that give rise to the patterns observed in a given 226 data set. Switching to this philosophy allows for techniques that match the daily activities of 227 social scientists in their endeavors to unravel the story of how humans operate. OOM pushes 228 the researcher to seek an inference to best explanation (Grice et al., 2017). This causal inference procedure differs from both NHST and Bayes yet are often conflated, which is 230 concerned with inferences to population parameters and their various assumptions underlying statistical tests (e.g., random sampling, normality, homogeneity of population 232 treatment differences, etc.). 233

Generally speaking, this approach can handle any type of data, including ordinal rankings and frequency counts, as all analyses are calculated in the same general fashion (see Valentine & Buchanan, 2013 for an example). This simplicity occurs because OOM works on

the deep structure of the data which is a binary coding technique similar to dummy and effect coding. Deep structures are matrices of zeros and ones which can be efficiently 238 manipulated to investigate patterns within the data. The most important values from any 239 OOM analysis are the PCC (percent correct classification) values. These values represent the 240 summation of how well an individual's responses matched the stated or expected pattern or, 241 in the case of causal modeling, how many of the individuals conformed to a given cause. 242 Complete matches are the proportion of observations that match the researcher-designated 243 pattern on all dimensions. For example, in a three-level Ordinal Pattern Analysis (OPA), a person would be tallied as a "complete match" if the ordinal pattern of his/her data matched 245 the expected ordinal pattern across all three levels. For example, imagine we have set a 246 pattern that designates Time 1 < Time 2 < Time 3. Person A has values of 3, 4, and 5 at 247 timepoints 1, 2, and 3, respectively, while person B has values of 4, 5, and 2. Person A matches the pattern completely, and is therefore counted in the PCC value. Person B, however, matches only the first part of the pattern (time 1 less than time 2) and is not counted in the PCC value. However, while person B matched the first part of our pattern 251 (time 1 less than time 2), they did not match on the third point of our pattern (time 2 less 252 than time 3); thus, they would not be counted in the PCC value. As the PCC is simply the 253 percentage of individuals in a sample whose responses match the expected ordinal pattern 254 perfectly, its computation is therefore not based on means or variances, but on the basis of 255 the observations themselves. The PCC value replaces all of the conventional values for effect 256 size used in statistical analyses. 257

The analysis we focus on here (OPA) does not form any type of linear or nonlinear
equation or regression, but simply looks for those individuals who match the expected
ordinal pattern (Grice, Craig, & Abramson, 2015). The main point of the analysis, then, is
to see how many people fit the expected pattern which is based on a causal theory. If all
causes are accounted for in the study and observations have been made with sufficient
precision and accuracy, then 100% of the persons should fit the expected pattern; otherwise,

a lower PCC value will be expected and it is up to the researcher to determine how high a PCC must be in order to support an inference to the causal mechanism.

In OOM, traditional p-values are no longer utilized (Grice, 2011). As a secondary form of reference value, a chance value (c-value) is obtained, which is a type of randomization test 267 in which the researcher determines the number of randomized trials for the test (e.g. 1,000 or 268 5,000 randomized versions of actual observations). This procedure is akin to permutation 269 tests, where PCCs are computed for the randomized data to form a distribution. The 270 observed PCC is then compared to these values, and the c-value (which is an empirical 271 probability) is determined. If the randomized data sets fit the pattern as well as or better 272 than the actual data does, the c-value will be high (close to 1). Low c-values (close to 0) 273 indicate a pattern of observations that is improbable (i.e., unlikely produced by chance) 274 when compared to randomized versions of the same data. Although low c-values, like low 275 p-values, are desirable, c-values do not adhere to a strict cut-off and should be considered a 276 secondary form of confirmation for the researcher that their results are distinct. 277

278 Typical Procedure

279

280

281

282

283

284

OPA is analogous to repeated measures ANOVA and contains two steps.

1) Designate the expected ranked pattern: each variable as being higher, lower, or equal to the other variables. For instance, for our analyses we defined the following pattern of individual responses X_i , whereby the first time point should be less than the second time point which should be less than the third time point. This pattern can be operationalized as follows:

$$X_{i_1} < X_{i_2} < X_{i_3}$$

2) Analyze the data using OPA. Consider the PCC (the percentage of individuals matching the ordinal hypothesis) and c-values in light of the data and use your best judgment as to whether or not the data conform to the expected pattern. This analysis only requires the assumption that the data exists such that a pattern may be designed.

As with all of these methodologies, limitations do exist. This approach is largely concerned with patterns of responses, not with magnitudes of differences, which may be an integral piece of information to some researchers. Unlike all approaches mentioned before, we do not discuss the probability of some data given our hypothesis here, and instead focus on the observed responses of the individual and how it may or may not behave as expected. Finally, similar to the Bayesian analysis, long-run error rates are not discussed in this methodology.

A Simulation Study

297 Simulated Data

285

286

287

288

296

In this study, we generated 20,000 datasets by manipulating sample size and effect size 298 for a repeated measures design with three levels. A repeated measures design was chosen as 299 it is widely used across many disciplines of psychology. These datasets were created using 300 the mvtnorm package in R (Genz et al., 2017), and all code for simulations can be found at 301 https://osf.io/u9hf4/?view_only=1caa9092868b4d7aadb9a83a31a979cd. Interested readers 302 can easily adapt the R code to incorporate different research designs. Likert data, ranging from 1 to 7, was created by rounding mvtnorm estimates to whole numbers and truncating any data points out side of the appropriate range (i.e., values < 1 were rounded to 1, and values > 7 were rounded to 7). We specifically chose Likert-type data as this data type is 306 one of the most common data types utilized by most social scientists. Additionally, we add 307 to the literature as other simulations have chosen to use completely continuous data (i.e., 308

simulated numbers are often precise to 10+ decimals, which is unlikely for traditional 309 sampling). The simulated data did increase in skew with this procedure from approximately 310 no skew (i.e., <0.01) to approximately 0.40 for the smallest and no effect conditions; 311 however, these values closely resembled a normal distribution with the use of mvtnorm. The 312 population means for each level were set to 2.5, 3.0, and 3.5, and pairwise effect sizes (e.g., 313 the comparison between time 1 v. time 2 and time 2 v. time 3) were manipulated by 314 adjusting the standard deviation to create negligible effects (SD = 3.39, d = 0.10), small 315 effects (SD = 3.00, d = 0.20), medium effects (SD = 0.50, d = 0.50), and large effects (SD = 0.50, d = 0.50) 316 0.10, d = 0.80) using Cohen (1992)'s traditional guidelines for d interpretation. The smallest 317 effect size was set such that Likert style data could still be retained with the smallest 318 possible effect size. Sample size was manipulated at 10, 30, 100, 500, and 1,000 data points. 319 All combinations of the five sample sizes and four effect sizes were created, and each dataset was simulated 1,000 times, totaling 20,000 datasets. 321

The advantage of using mvtnorm and set SDs for each group was the ability to approximate the assumptions of normality by randomly generating from a multivariate normal distribution, and homogeneity by setting equal SDs for each group. In a repeated measures design, the assumption of sphericity was met by setting the correlations between levels in mvtnorm to zero. By maintaining the lowest level of relationship between levels, we additionally controlled for power and examined situations of significance given the lowest power scenario. During the data simulation, the standard deviation of the difference scores was examined to maintain differences greater than zero, especially for low N simulations.

330 Analyses Performed

Descriptive Statistics. Means, mean differences between levels, and the confidence intervals for each mean can be found in the complete dataset online,

https://osf.io/u9hf4/?view_only=1caa9092868b4d7aadb9a83a31a979cd. For each simulation,

we also calculated d values using the standard deviation of the difference score as the
denominator (d_z , Lakens, 2013). The MOTE library was used to calculate the non-central
confidence interval for each d value as well (Buchanan, Valentine, & Scofield, 2017;
Cumming, 2014). This data was mainly used to determine if simulations were meeting
expected values overall.

Parametric NHST - Repeated Measures ANOVA. Repeated measures

ANOVA using the ezANOVA() function in the ez library was utilized with type three sum of

squares (Lawrence, 2017). This style of ANOVA is used to compare the same individuals

across multiple or all conditions in an experiment. The null hypothesis states that there are

no significant differences between population means, and the research hypothesis posits that

there are differences between some population means, but does not specify which population

means may differ, just that one or more will differ as the alternative. This test uses the Fdistribution focusing on p values.

To determine where differences may exist, post hoc dependent t-tests are normally 347 analyzed in the event of a significant F-ratio. We did not run all pairwise comparisons, 348 instead focusing on the linear trend simulated by comparing level one to two and level two to 340 three. This set of comparisons also controlled the effect size between comparisons, as 350 comparing level one to three would have doubled the effect size. However, we assumed that 351 typical researchers might compare all three pairwise combinations in practice and used a 352 Bonferroni correction across all three possible pairwise combinations to calculate p values for 353 post hoc tests. Therefore, while we only discuss the two comparisons, we utilized the more stringent cutoff of the Bonferroni correction as we believe this procedure would be how the majority of researchers would handle the data. Interested readers can find all three 356 comparison values in the complete dataset online. Following traditional usage, a p-value of 357 less than .05 was binned as significant, whereas p-values ranging from .10 to .05 were binned 358 as marginally significant. Any p-values larger than .10 were binned as non-significant. A 359

second set of p-value comparisons was calculated given Benjamin et al. (2018)'s suggestion to change α criterion to less than .005. Any p-value less than .005 was binned as significant, while data ranging from .005 to .10 was marginal or suggestive, and p > .10 was non-significant.

Bayesian Analysis: Bayes Factor. We compared a null model with one grand 364 mean for all three levels to an effects model wherein means were allowed to differ using the 365 BayesFactor package (Morey & Rouder, 2015). The default in this package is a Jeffreys prior with a fixed rscale (0.5) and random rscale (1.0). BF were calculated, and follow up t-test BFs were computed for the same two comparisons as in the previous models using default priors from the BayesFactor package (e.g., Jeffreys prior for population variance, Cauchy prior for standardized effect size). To compare Bayesian results to other statistical methods, 370 we used recommendations from Kass and Raftery (1995) to bin results into weak evidence 371 (BFs < 3), positive evidence (e.g., akin to marginal p-values, BFs = 3-20), and strong 372 evidence (BFs > 20). We must stress here that BF interpretation should focus on 373 understanding the odds of model ratios, not necessarily the presence or absence of an effect. 374 However, given that we wanted to compare the conclusions one would reach given this data 375 in a Bayesian paradigm to that of a frequentist paradigm, these bins are used as a convenient 376 comparison to the frequentist procedures using set criteria for interpretation (Morey, 2015). 377 Should any reader become curious how a different set of binning values affect our analyses, 378 all code and data are at their disposal at 379 https://osf.io/u9hf4/?view only=1caa9092868b4d7aadb9a83a31a979cd, and this manuscript 380 was written with the papaja package allowing one to view the code inline with this text 381 (Aust & Barth, 2017). 382

OOM: Ordinal Pattern Analysis. An R script of the Ordinal Pattern Analysis from Grice et al. (2015)'s OOM program was provided from Sauer and Luebke (2016). We set the expected ranked pattern as level one less than level two less than level three. Once

this pattern was defined, we then analyzed the data to see if each individual's set of 386 observations matched this expected ordinal pattern. PCC values were generated, and 387 c-values were computed by randomizing the data 1,000 times. Solely for purposes of 388 comparison, we used the following significance coding schema: significant studies had a high 389 PCC value (.50 < PCC < 1.00) and a low c-value (c < .05), marginal studies had a high 390 PCC value and a moderate c-value (.05 < c < .10), and non-significant studies had low PCC 391 values (PCC < .50), regardless of their c-values. Again, we must stress that this paradigm 392 eschews binning estimates and that our use of bins was a) discussed and decided upon before 393 data analysis, and b) created only for the purposes of comparing this new methodology's 394 possible conclusions to that of a frequentist framework. We welcome interested readers to 395 explore the data more, defining their own bins and viewing the affects, by viewing and 396 editing our code online.

Results

99 Percent of Estimates

For all simulations, we first binned the estimates into significant, marginal, and 400 non-significant effect categories as described in the Analyses Performed section above. Next, 401 we calculated the percentage of these analyses that would be classified into each of these 402 categories, separated about by statistical analysis, sample size, and effect size. These 403 estimates were binned across both the overall and follow up post hoc tests, and the combined 404 data are presented for this analysis. Since all three categories of binning total to 100%, we present only the significant and non-significant results. Significant critical omnibus estimates are presented in Figure 1. All figures discussed in this manuscript may be viewed as 407 interactive graphics on our OSF page through a provided Shiny app. In Figures with sample 408 size on the axes, we log transformed N to allow for visual distinction between sample sizes, 409 as smaller N values were compressed when using the N=10 to 1000 on the axis. Both N 410

and $\log(N)$ can be found in the Shiny app, along with the ability to zoom in to specific ranges of sample size.

For negligible effects at p < .05 (solid lines), we found that NSHT analyses showed a 413 predictable Type I error bias, in that they detected significant estimates with extremely 414 small d values as sample size increased. Binned BF values showed a similar pattern, but 415 were more conservative with less percent significant estimates. OOM analyses were the most 416 conservative, essentially never detecting an estimate in the negligible effect simulations. 417 Small effect sizes showed the same pattern for NHST, BF, and OOM results, with the proportion of significant estimates increasing more rapidly and asymptoting at a smaller sample size than negligible effects. At medium effect sizes, NHST analyses nearly always detected significant estimates, while BF and OOM analyses would have been considered 421 significant around 75% of the time. Interestingly, with large effect sizes, OOM analyses 422 mirrored NHST by always detecting estimates, and BF analyses were generally more 423 conservative except at the largest sample size. Figure 1's dashed lines indicate the results if 424 values were binned at p < .005, and the differences between these results were very subtle. 425 Lowering α reduced the number of significant estimates at small N values for all four effect 426 sizes, with more pronounced differences at negligible and small effect sizes. However, the 427 graphs converged to the same conclusion that large enough sample sizes could produce 428 significant results at negligible and small effect sizes. 429

Figure 2 portrays the results for non-significant binned simulations, which were the same for both α criterion. Across all effect sizes, BF and NHST showed similar results, where non-significant estimates were detected at lower sample sizes for negligible and small effect size simulations. At medium and large effect sizes, almost all estimates would have been considered significant, therefore, detection rates for non-significant estimates were around zero. OOM displayed a conservative set of findings, showing nearly 100% non-significant estimates at negligible and small effect sizes (mirroring results from Figure 1).

At medium effect sizes, approximately a quarter of estimates were non-significant, illustrating the conservative nature of OOM interpretations.

Figure 3 depicts the relationship between the effect size of time 1 minus time 2 and the 439 corresponding PCC values. These metrics appear to represent different concepts where effect 440 size measures the magnitude of the difference between two data points while PCC disregards 441 magnitude and represents the proportion of the sample following the given ordinal pattern 442 across all three time points. Given these differences, it is interesting how well these two 443 measures converge together. As sample size increases, estimates for both d and PCC become 444 more precise (i.e., smaller range, closer to the simulated effect size). We believe that PCC 445 offers researchers the ability not only to confirm that their effect size is reasonable, but also 446 to better understand the pattern their data are following, especially if an observed effect size 447 contradicts previous literature. For example, let us assume there is previous literature that 448 states that a small positive effect exists, such that responses should increase from time 1 to 449 time 2. Under conditions of a true small effect (d=-0.20) and sample size of 30, our graph 450 shows us that it is possible to obtain a positive medium effect size (d = 0.50; indicating the time 1 is more extreme than time 2). Upon finding these contradicting results, the researcher could further seek to understand the pattern their data are following by computing the PCC value for the experiment. The PCC value for this example would be above .50, indicating that, in over half of respondents the values for time 1 are less than time 2 (in turn less than 455 time 3, as it measures the entire pattern), even though magnitude of change suggests that 456 time 1 is larger than time 2. This gives the researcher a richer piece of information, which 457 can help to describe their results in a more nuanced fashion. 458

459 Percent Agreement

A goal of this project was to expand the toolbox of options for researchers to determine
what evidence supports their hypotheses by examining multiple methodologies. We

calculated the percent of time that all analyses agreed across overall and *post hoc* comparison estimates. Figure 4 illustrates the pattern of 100% agreement on effects for critical omnibus tests only at each sample size and effect size. Figure 5 portrays the results for *post hoc* tests, which only uses NHST and Bayes Factor analyses, as OOM does not have a *post hoc* test (i.e., the test is a pattern analysis that presupposes the expected direction of *post hoc* tests).

When effect sizes were negligible and for small effects, agreement was best across small 467 samples and decreased across sample size, as NHST was overly biased to report significant 468 estimates and OOM and BF were less likely to do so. For medium and large effect sizes, 469 50-75\% agreement was found, usually regardless of sample size. Additionally, we found that 470 for negligible, small, and medium effects, agreement for post hoc tests was higher than 471 agreement for overall comparisons. The post hoc comparisons for levels 1 to 2 and levels 2 to 472 3 were less likely to be binned as significant across negligible and small effects, so the 473 agreement levels were higher for these individual comparisons due to non-significant follow 474 up tests. The critical omnibus test was more likely to be significant due to the inclusion of 475 effect of comparisons between level 1 and 3, which were double the effect size. However, 476 these post hoc comparisons do not include the conservative significant binning from OOM, which decreased critical omnibus 100% agreement seen in Figure 4. Again, the differences 478 between p < .05 and p < .005 were minimal. Complete tables of percentages of binning across critical omnibus and post hoc tests, along with agreement percentages broken down by 480 bins can be found at https://osf.io/u9hf4/?view only=1caa9092868b4d7aadb9a83a31a979cd. 481

482 Criterion Comparison

As the relationship between BF and p-values is already well documented, we will not discuss them here beyond stating that we found the expected pattern shown in previous work (Rouder et al., 2012), and that individuals who wish to view this comparison, as well as all the other comparisons discussed here should visit our interactive Shiny application at our

OSF page. Of interest was the comparison of OOM indices to traditional NHST and 487 Bayesian indices. First, in Figure 6, PCC values are plotted against log BF values and 488 p-values. The log of BF was taken to include all values on a viewable axis, and all infinity 489 values were windsorized to the next highest point. Increasing sample size is shown by 490 increasing point size and lighter colors. Additionally, since OOM values are a combination of 491 PCC and c-values, c-values below .05 are shown as Xs instead of dots. Therefore, all values 492 $PCC \ge 0.50$ that are also denoted as Xs would be considered significant in this example. 493 The provided Shiny application uses color to distinguish sample size differences, as well as includes options to create each combination effect size and criterion individually. Only two 495 graphs are provided here to save space. 496

In Figure 6, the left hand column portrays the relationship between log BF values and 497 PCC values in negligible and medium effect sizes. With negligible effect sizes, we found large 498 variability in PCC values across a small span of BF values while sample sizes remained low, 499 but as N increased, we saw that the range of PCC values narrowed considerably with 500 increasing BF values. Therefore, as sample size increased, the PCC values constricted, while 501 BF values expanded. A similar pattern appeared when viewing the medium sample size 502 graph, as again PCC values became less variable with increased sample size, and BF tended 503 to increase both in variability and in value as the sample size grew. Here, we can see a 504 benefit of PCC, along with c-values, as increasing sample size portrayed more precision in 505 PCC, instead of the increased variability found in BF. 506

It is also important to note that within the negligible effects graph, while many of
these PCC values reached high values, that these values did not denote patterns that would
necessarily be seen as unique. c-values were a secondary measure of evaluation that
eliminated a number of these matches from being considered meaningful. A large majority of
points with larger sample sizes on the figure included low chance values, however, the PCC
values for these simulations were lower than a meaningful percent used for cutoff criterion.

This two-step process helped to weed out effects that were negligible, especially at larger sample sizes.

Additionally, we compared p-values and PCC values, which are illustrated on the right 515 hand side of Figure 6. Again, PCC values showed far more variability with small sample 516 sizes, and the p-values associated with these smaller sample sizes were also quite variable. 517 Importantly, even when an effect was negligible, PCC values become less variable with 518 increasing sample size. PCC values also indicated that there was little evidence of the 519 hypothesized pattern by shifting toward zero. p-values decreased in variability at high 520 sample sizes and shifted toward minuscule values, thus, pointing toward rejecting the null 521 hypothesis. With medium effect sizes, both p-values and PCC values were variable at small 522 sample sizes. At larger sample sizes, p-values decreased towards floor effects (i.e., closer to 523 zero), while PCC values simply narrowed in range shifting slight above .50. The benefit of 524 multiple criteria evaluation here was clear, as p-values increasingly indicated significance as 525 sample size increased, PCC values were not effected in this way and thus presented a more 526 stable picture of the presence of an effect. While multiple criteria may not completely reduce the interpretation of false positives in the literature, the relationship between these values illustrated that multiple indices can provided a clearer picture of the evidentiary value available in a study.

531 Limitations

Within any study a number of limitations exist. The largest limitation of our study is
that we chose to focus on a simple three level repeated measures ANOVA design. The
benefit to this focus is the simplicity of understanding the relationship between analyses,
while also using a well understood NHST procedure. However, is possible that these same
relationships may or may not exist in alternative design contexts. Additionally, our choices
for classification of significant effects for p-values, BF, PCC, and c-values was based on what

we believe a reasonable researcher may designate; however, these classifications may vary in
the real world. We provide open access to our simulations and code so that an interested
party can tinker with these choices. We believe the global conclusions would likely be similar
across changes, however, the specific percentages and patterns would likely differ. Finally,
due to the specification of our simulation we did not violate any statistical assumptions. It is
possible that the violation of these assumptions may cause changes in the relationships we
see here.

Discussion

562

This manuscript was designed to showcase two alternative paradigms to NHST 546 researchers and to compare the conclusions these alternative methodologies might make in a 547 given data environment to those NHST would make. We believe that the awareness of 548 multiple methodologies might assist in strengthening our conclusions and improving 549 reproducibility by giving researchers the ability to identify an optimal method given the 550 question at hand. Further, we believe that should a researcher utilize multiple methodologies 551 (e.g., analyzing and reporting both a NHST p-value as well as an OOM PCC value) that 552 these estimates in tandem can help readers to weight these various forms of evidence and 553 arrive at a more robust conclusion. We found that changing the threshold at which p-values are deemed significant had little to no effect on conclusions, especially at large sample sizes, regardless of effect size. This finding is notable as the article by Benjamin et al. (2018) 556 states that an increase in sample size is likely to decrease false positives "by factors greater 557 than two" (p. 10), and work by Pericchi and Pereira (2016) state that an adaptive level of 558 significance would be beneficial in these circumstances, neither of which are supported by our 550 simulations. Our science will not grow by moving the significance line in the sand, as this line 560 has already been shown to have "no ontological basis" (Rosnow & Rosenthal, 1989, p. 1277). 561

Instead, we need to embrace the multitude of perspectives available to us and to begin

to employ these diverse approaches. While NHST can still serve us well when properly 563 utilized, it is important for researchers to understand that different methods seek to answer 564 different questions, and that we need to ensure that we are using the right method to answer 565 a given question. When evaluating evidence in order to answer these questions we must be 566 wary of looking for significant differences and focus instead on finding meaningful differences. 567 By combining these approaches we may be better able to qualify the strength of our evidence 568 and discuss a more nuanced version of our data. Additionally, while all of these methods 569 have drawbacks, when used in combination these methods can begin to overcome many of 570 these limitations. For instance, given a large sample size, we would expect BF values to be 571 very large and p-values to be very small, both indicating that the null model/hypothesis 572 should not be supported. However, if we also have a PCC value of .30, we may decide that it 573 is possible that this effect is very small and possibly negligible. This multifaceted approach can help to curb our enthusiasm over small or negligible effects that may not be practically 575 meaningful and possibly may not replicate. Regardless if analyses agree or disagree on the presence of an effect, a researcher can investigate the direction and size of the effect, the 577 proportion of data that agrees or disagrees with the direction of the effect, and discuss 578 conclusions accordingly. Each methodology behaves slightly differently in given data 579 environments, which might begin to highlight meaningful differences when discussed together. 580

Some may contest that all of these analyses are capable of being hacked, like p-values, through researcher degrees of freedom, choice of priors, or pattern choice, among other actions (Simmons et al., 2011). Transparency throughout the research process is key to eliminating these issues, as α changes may only encourage bad research practices with the current incentive structure on publishing. Although we have the capability to share research across the world, research often still occurs behind closed doors. The Open Science Framework grants insight into research processes, allowing researchers to share their methodologies, code, design, and other important components of their projects. In addition to posting materials for projects, pre-registration of hypotheses and methodology will be an

important facet in scientific accountability. Further, with increased transparency editors and other researchers can weigh the evidence presented according to their own beliefs.

Our key suggestion in this project is the redefinition of evidentiary value. The current 592 focus on p-values has shown to be problematic, as many of the studies from the Open 593 Science Collaboration (2015) do not replicate at p < .05 or p < .005 (Lakens et al., 2018). 594 With the change in transparency mentioned above, publishing research with solid research 595 designs and statistics, regardless of p-values, will allow for a broader range of evidence to 596 become available. Publishing null findings is critical in replication and extension for discovering the limits and settings necessary for phenomena. Registered replications and reports will allow studies to be accepted prior to results being known, thus allowing researchers to focus on experimental design and hypotheses apriori instead of p-values post 600 hoc. Reports should describe multiple indicators of evidence, such as effect sizes, confidence 601 intervals, power analyses, Bayes Factors, and other descriptive statistics (Finkel, Eastwick, & 602 Reis, 2015; Nosek & Lakens, 2014; van't Veer & Giner-Sorolla, 2016). 603

A misunderstanding of statistical power still plagues psychological sciences (Bakker, 604 Hartgerink, Wicherts, & van der Maas, 2016), and the effect of sample size, especially small 605 ones, was shown here by comparing the criterion available in these analyses. Often, 606 individual research labs may not have the means to adequately power a proposed study. 607 Multilab studies and collaboration with other scientists is fundamental to alleviating these 608 issues, while encouraging interdisciplinary science. Collaboration increases our statistical abilities, as every researcher cannot be expected to be proficient in all methods and analyses, but teams of researchers can be assembled to cover a wider range of statistical skills to provide adequate estimates of evidence in their reports. We understand that there may be 612 resistance to the implementation of multiple methodologies as these new methodologies take 613 time and effort to learn. However, through the use of free programs (JASP, R, OOM, Shiny) 614 and tutorials (YouTube, Coursera, http://www.statstools.com), we believe all researchers are 615

capable of learning these analyses. We believe that through the expansion of our analytical knowledge and application of these new methodologies, we can begin to attenuate some of the strain currently placed on psychological science and to increase the strength of evidence in our discipline.

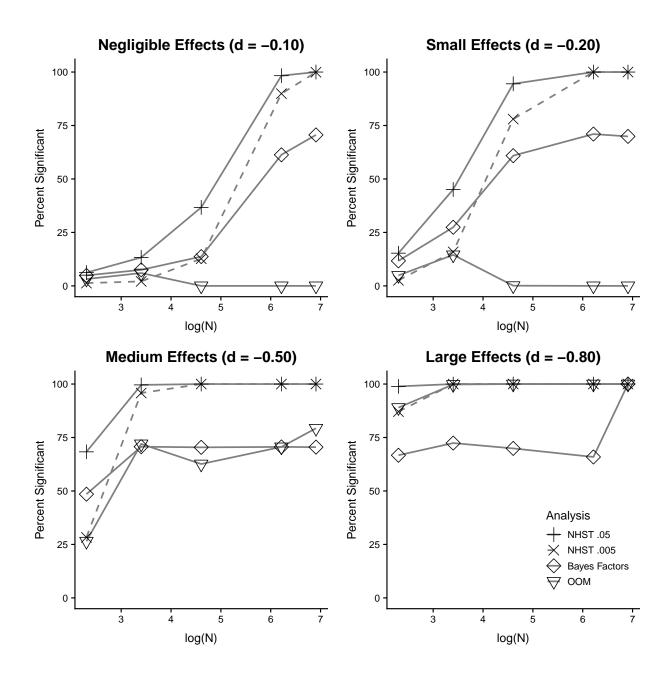

Figure 1. For NHST analyses only, percent of significant estimates at p < .05 (solid) and p < .005 (dashed) for each analysis given effect size and sample size.

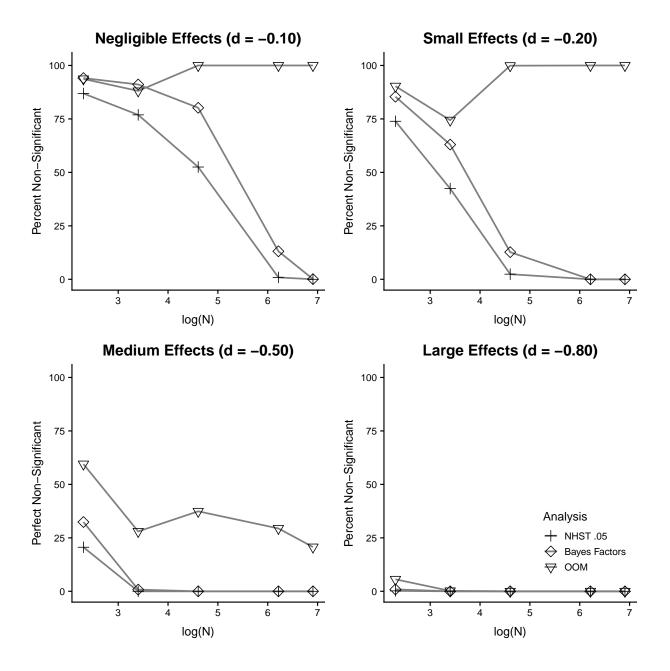

Figure 2. Percent of non-significant effects for each analysis given effect size and sample size.

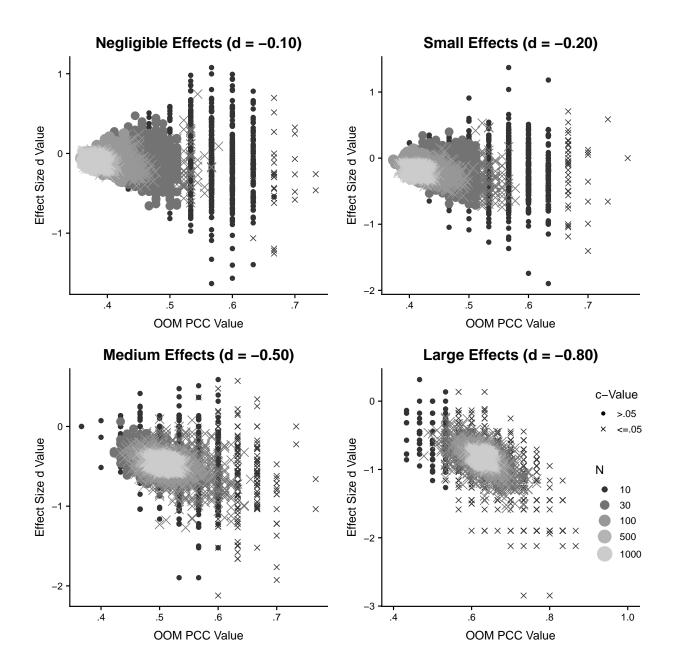

Figure 3. PCC and c-values plotted against observed effect size (d-values) given effect size and sample size conditions. Xs indicate simulations with c-values < .05, which were binned as significant if they were found in conjunction with PCC values over .50. Point size and color indicates sample size wherein larger samples are lighter colors. Please note that the key for the entire set of graphics is in the bottom right hand corner.

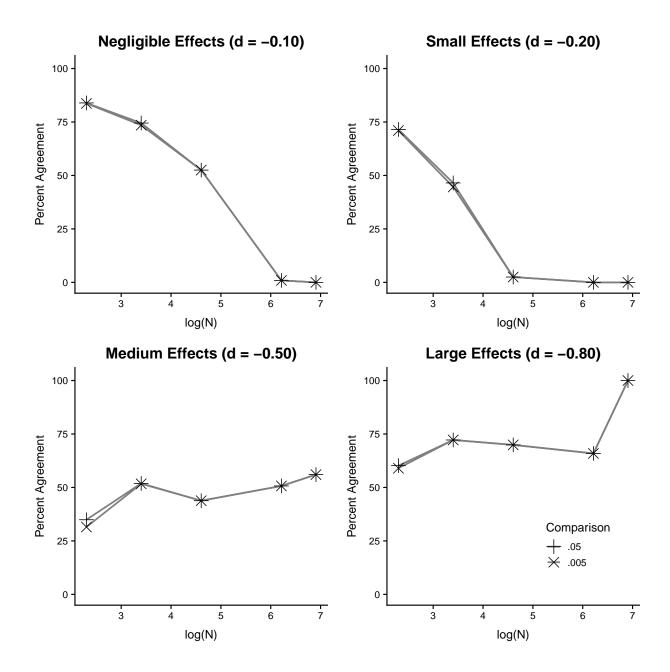

Figure 4. Percent of agreement across all analyses given effect size and sample size for omnnibus tests.

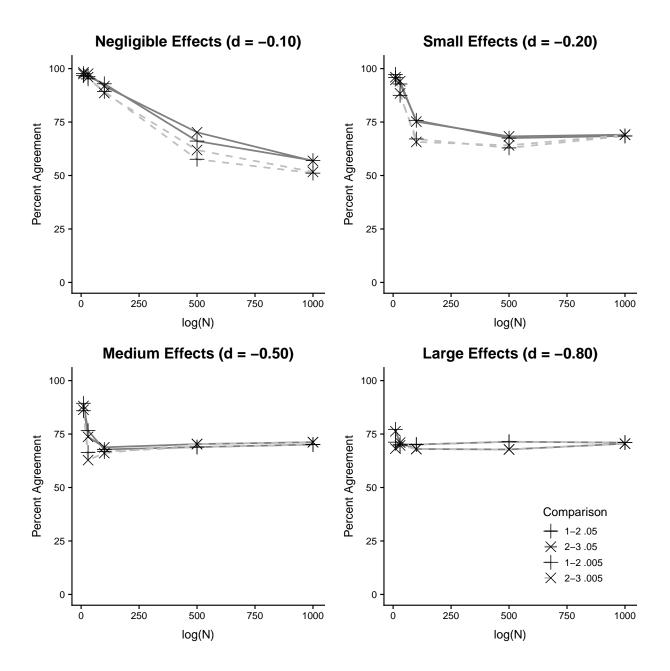

Figure 5. Percent of agreement across each analysis given effect size and sample size posthoc tests with p < .05 (solid) and p < .005 (dashed). Note that this graph only compares the NHST and BF conclusions.

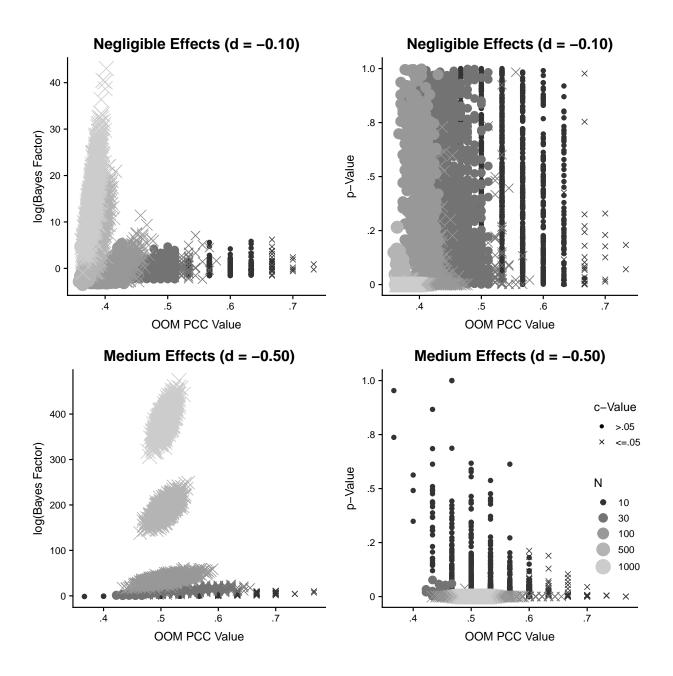

Figure 6. PCC and c-values plotted against p and BF values for negligible and medium effect size conditions. Xs indicate simulations with c-values < .05,which were binned as significant if they were found in conjunction with PCC values over .50. Point size and color indicates sample size wherein larger samples are lighter colors. Please note that the key for the entire set of graphics is in the bottom right hand corner.
