17 Abstract

Modeling, evidence

Null hypothesis significance testing is frequently cited as a threat to the validity and 18 reproducibility of the social sciences. While many individuals suggest we should focus on 19 altering the p-value at which we deem an effect significant, we believe this suggestion is 20 short-sighted. Alternative procedures (i.e., Bayesian analyses and Observation Oriented 21 Modeling; OOM) can be more powerful and meaningful to our discipline. However, these 22 methodologies are less frequently utilized and are rarely discussed in combination with 23 NHST. Herein, we discuss the historical roots, procedures, and assumptions of three 24 methodologies (NHST, Bayesian Model comparison, and OOM), then compare the possible 25 interpretations of three analyses (ANOVA, Bayes Factor, and an Ordinal Pattern Analysis) in various data environments using a simulation study. Our frequentist simulation approach generated 20,000 unique datasets which varied sample size (Ns of 10, 30, 100, 500, 1,000), 28 and effect sizes (ds of 0.10, 0.20, 0.50, 0.80). Through this simulation, we find that changing the threshold at which p-values are considered significant has little to no effect on conclusions. Further, we find that evaluating multiple estimates as evidence of an effect can allow for a more robust and nuanced report of findings. These findings suggest the need to 32 redefine evidentiary value and reporting practices. 33 Keywords: null hypothesis testing, p-values, Bayes Factors, Observation Oriented 34

Beyond p-values: Utilizing Multiple Methods to Evaluate Evidence

36

Recent events in psychological science have prompted concerns within the discipline 37 regarding research practices and ultimately the validity and reproducibility of published 38 reports (Etz & Vandekerckhove, 2016; Lindsay, 2015; Open Science Collaboration, 2015; Van 39 Elk et al., 2015). One often discussed matter is over-reliance, abuse, and potential hacking of p-values produced by frequentist null hypothesis significance testing (NHST), as well as 41 misinterpretations of NHST results (Gigerenzer, 2004; Ioannidis, 2005; Simmons, Nelson, & Simonsohn, 2011). We agree with these concerns and believe that many before us have voiced sound, generally accepted opinions on potential remedies, such as an increased focus on effect sizes (Cumming, 2008; Lakens, 2013; Maxwell, Lau, & Howard, 2015; Nosek, Spies, & Motyl, 2012). However, other suggestions have been met with less enthusiasm, including a recent article by Benjamin et al. (2018) advocating that researchers should begin thinking only of p-values less than .005 as "statistically significant", thus changing  $\alpha$  levels to control Type I error rates. Additionally, Pericchi and Pereira (2016) promote the use of fluctuating  $\alpha$  levels as a function of sample size to assist with these errors. We argue it is not the threshold, or critical p-, that needs to be rethought when seeking evidence, but rather if a p-value should be utilized at all, and, if so, what that p-value can tell you in relation to other indicators. While NHST and p-values may have merit, researchers have a wealth of other 53 statistical tools available to them. We believe that improvements may be made to the sciences as a whole when individuals become aware of the tools available to them and how 55 these methods may be used—either alone or in combination—to strengthen understanding and conclusions. These sentiments have been shared by the American Statistical Association 57 who recently held a conference focusing on going beyond NHST, expanding their previous stance p-values (Wasserstein & Lazar, 2016). 59 Therefore, we undertook this project to show researchers how two alternative 60 paradigms compare to NHST in terms of their methodological design, statistical 61 interpretations, and (WHAT WORD SHOULD GO HERE?) robustness. Herein, we will

discuss the following methodologies: NHST, Bayes Factor comparisons, and Observation
Oriented Modeling. The three approaches will be compared via this simulated data using a 3
timepoint repeated measures design with a Likert-type scale as the outcome variable. One
goal of this study is to introduce social scientists to Observation Oriented Modeling (OOM),
as it is a relatively new paradigm that is readily interpretable and, as we will show, useful in
these contexts. Additionally, we aim to discuss the conclusions these three methods would
make given the same data, and to compare how often these methodologies agree within
different data environments (i.e. given varying sample sizes and effect sizes). We hope that
by discussing these methodologies in terms of a simple statistical analysis researchers will be
able to easily compare and contrast methodologies. For this discussion, it is important to
understand their historical background, procedural steps, and limitations, which are outlined
below. After this discussion, we describe a simulation study comparing methodologies and  $\alpha$ criteria, and end with potential implications for researchers.

## **Null Hypothesis Significance Testing**

### 77 History

76

Many attribute the frequentist NHST procedure to Ronald A. Fisher (Fisher, 1932).

However, Fisher's ideas are a far cry from the NHST procedure implemented today. Fisher believed in creating one "null" hypothesis, which he described as a hypothesis to be "nullified", or shown incorrect, not as a zero-difference hypothesis (Lehmann, 2011). He also believed that the use of any omnibus level of significance showed a "lack of statistical thinking" (Gigerenzer, Krauss, & Vitouch, 2004). He instead believed we should report the exact significance value of a test and let others make their own decision about the claims, which is more in line with the typical reporting recommendations provided by the American Psychological Association (American Psychological Association, 2010). Fisher spoke of this work to William Gosset, the man who created the Student's t-test and contributed work on the correlation coefficient (Lehmann, 2011). Gosset in turn discussed the idea of an

alternative hypothesis, a piece not included in Fisher's procedure, with decision theorist Egon Pearson.

From this discussion, Egon Pearson and Jerzy Neyman created Neyman-Pearson 91 decision theory. This theory consists of two hypotheses (i.e., null and alternative) and a binary decision criteria (i.e., significant or not, Lehmann, 1993). However, this procedure created the possibility of researcher decision errors (Dienes, 2008). A researcher may falsely reject the null hypothesis (Type I error,  $\alpha$ ) or falsely fail to reject the null (Type II error,  $\beta$ ). 95  $\alpha$  levels set the binary decision criteria, which are used as the critical p-value for hypothesis 96 testing (i.e., p < .05), and are thus seen as evidence to reject the null hypothesis.  $\beta$  and 97 power are inherently linked (Power =  $1-\beta$ ), so as the likelihood of finding a true effect 98 increases beta decreases (Maxwell & Delaney, 2004). Although  $\alpha$  values can be chosen to be 99 quite small, and methods (such as decreasing error variance or using a 1-tailed test as 100 opposed to a 2-tailed test) can decrease  $\beta$  values as well, a researcher can never know if they 101 have made the correct decision, or a decision error. Thus, Neyman and Pearson clearly state 102 that a hypothesis should not be blindly supported based solely on the estimates of one 103 statistical test, and that replication and reproduction of results are imperative. The recent 104 work of the Open Science Collaboration (2015) has also highlighted the need for replication 105 studies and interpretation of results in an appropriate context. Additionally, Neyman and 106 Pearson emphasized that use of set  $\alpha$ s and  $\beta$ s is illogical and sought instead for researchers 107 to adjust their analysis to the needs of the particular task at hand (Gigerenzer, 2004).

### 109 Typical NHST Procedure

Neither Fisher's hypothesis testing, nor Neyman-Pearson decision theory quite match
the NSHT procedure as it is taught and applied today. Psychologists have largely adopted
an amalgamation of the two approaches. Here, we attempt to outline what we believe is the
most appropriate way to carry out the traditional NHST procedure in the context of a
repeated measures ANOVA with three levels, although we note that this set of steps is not

necessarily how researchers carry out the procedure in practice: 115

117

1) Create two hypotheses, one to be "nullified" and one "alternative" hypothesis. Within 116 this repeated measures framework, most researchers would define a null hypothesis  $(H_0)$  that indicates of all three time point population means are equal. The alternative 118 hypothesis  $(H_A)$  would then be that not all of the population means are equal. These 119 can be operationalized in our example data as follows (note that for  $H_A$  we use a 120 common short hand to denote the model): 121

$$H_0: \mu_1 = \mu_2 = \mu_3$$

$$H_A: \mu_1 \neq \mu_2 \neq \mu_3$$

- 2) Select an  $\alpha$  level that is appropriate given the context of your research, your analysis plan, 122 and your research question, and do not blindly adopt an omnibus critical p-value (Lakens et 123 al., 2018). 124
- 3) Compute your given analysis and identify the corresponding p-value. If your p-value is 125 less than the chosen  $\alpha$ , reject the null hypothesis and state that there appear to be 126 differences between some of your population means; however, if your p-value is greater 127 than or equal to the value selected, do not reject the null hypothesis, and state that a 128 difference between the population means could not be supported. 129
- While the NHST procedure itself gives us testable models, the specific analysis used to 130 test these models here, the repeated measures ANOVA with 3 levels, requires some additional assumptions that must be met before an analysis is begun (Tabachnick & Fidell, 132 2012). Data need to have no outlying or influential observations. Data must have a normal 133 sampling distribution, be linearly related, and have independent errors. Depending on the 134 statistical test, data must also be checked for equal variances, sphericity, and additivity. 135 These assumptions can be checked and, if necessary, corrected for; however, violations of 136

these assumptions can lead to inaccurate decisions and attenuated power. Further, with many analysis programs, data is required to have no missing values.

While this approach is widely used, there are many limitations associated with it. 139 First, this method can be sensitive to violations of the stated assumptions, and especially, if 140 the sample size is not large enough to create a normal sampling distribution (Tabachnick & 141 Fidell, 2012). Even if assumptions are met, or nonparametric tests are implemented (e.g., for 142 situations where a normal distribution assumption cannot be met), this methodology does not allow a researcher to state anything about the absence of an effect (i.e., no true differences). Through traditional NHST, one can only discuss evidence regarding the alternative hypothesis; one can never support the null hypothesis through this procedure. Given the recent findings regarding reproducibility, showing support for the absence of an effect can be even more crucial than showing support for the presence of an effect (Bakker, 148 Van Dijk, & Wicherts, 2012; Lakens, 2017). 149

### **Bayes Factors**

### 151 History

150

Thomas Bayes was a statistician and Presbyterian minister whose works are still 152 influential today (Bellhouse, 2004). Bayes' theorem solved the inverse probability problem, 153 namely that through the frequentist approach, one can only know the probability of data 154 existing given a hypothesis being true, never the probability of a hypothesis being true given 155 that the data exist (Dienes, 2008). Bayes' theorem allows one to calculate the probability of 156 a hypothesis given some data (posterior belief) by using how probable one believes the hypothesis to be before data was collected (prior belief) and how probable one believes the data to be given one's hypothesis (likelihood). Thus, with his theorem, researchers are able 159 to update (through the use of the likelihood) our initial beliefs (our prior) given some data 160 (Gelman, Carlin, Stern, & Rubin, 2013). Pierre-Simon Laplace pioneered Bayesianism and 161 advocated for a broader interpretation of this theorem (De Laplace, 1774). The use of 162

Bayesian statistics has been suggested as an NHST alternative (Dienes, 2014; Wagenmakers, 163 2007), but this approach has largely been undervalued in favor of frequentist methods as, 164 until recently, Bayesian analysis required considerable computational effort. However, today 165 we possess the technology necessary to efficiently conduct Bayesian analyses. While open 166 source software, such as R and JASP, require minimal learning to be able to effectively 167 operate (Morey & Rouder, 2015), researchers will need to invest more effort to understand 168 the focus and interpretation of Bayes Factor (BF) comparisons as they differ from traditional 169 NHST. 170

The Bayesian framework can be viewed as a continuum, with objective Bayesian 171 analyses on one end, and subjective Bayesian analyses on the other (Press, 2002). While this 172 topic could lend itself to its own manuscript, here we will simply summarize the two 173 endpoints, and discuss where our analysis may be perceived to fall on the line. Objective 174 Bayesian analysis is closest to frequentist theory, as the aim is to minimize the influence of 175 priors through the use of non-informative priors (such as Jefferys priors that are designed to 176 be invariant under reparameterization Datta & Ghosh, 1996); thus, the data is allowed to 177 maximally effect the posterior distribution. Further, objective Bayesian methods are 178 influenced by the same quality criteria that frequentist methods used, including Type I error 179 rate and power (Sellke, Bayarri, & Berger, 2001). On the other end, subjective Bayes 180 analyses include rigorously informed priors so that current knowledge can play a large role in 181 the posterior. Our current analysis splits these two; we do not utilize completely uniformed 182 (objective) priors, as we can adjust for basic knowledge of the constraints of our data type. 183 Given the usual lack of information about underlying distributions, a wider band of inclusion was used for prior information. The BayesFactor package (Morey & Rouder, 2015) assists 185 greatly in the choice of prior and is especially user-friendly for applied researchers, as it 186 makes use of recommended default priors that have been chosen to be safe to assume under 187 a broad range of data and topics (Rouder, Morey, Speckman, & Province, 2012; Rouder, 188 Speckman, Sun, Morey, & Iverson, 2009). Instead of conventional F, t, and p-values, a ratio 189

of the likelihood of the alternative model to the null is report, usually  $BF_{10}$ . For instance,  $BF_{10} = 20$  would indicate that the effects model is favored 20 to 1 over the null model. Conversely, if the  $BF_{10}$  were 0.10, the null model is favored 10 to 1 over the effects model. ## Typical Procedure

The procedure behind BF comparisons requires two steps.

1) One must design two models for the data. For our purposes, the first of these models will be the null model, which states that there are no differences between means ( $\mu$ ; i.e. all of our observed values  $X_i$ , regardless of which time point they were assessed at  $X_{ij}$ , arise from a normal distribution N with some mean  $\mu$  and variance  $\sigma^2$ ). The second model for these analyses is the effects model, which states that each mean ( $\mu$ ) is allowed to be different from the grand mean by some amount ( $\alpha$ ; as we now have observations being drawn from three potential normal distributions, all of which may have a different mean value, but the same variance). These can be operationalized as follows: CHANGE EFFECT (ALPHA) TO A DIFFERENT LETTER SO AS NOT TO CONFUSE WITH CUTOFF?

$$H_0: X_{ij} \sim N(\mu, \sigma^2)$$

$$H_A: X_{ij} \sim N(\mu + \alpha_i, \sigma^2)$$

In designing these models, one must choose the prior distributions that are believed to describe the data. Reasonable expectancies of where the data lie should be incorporated in this decision based on previous research into the studied phenomena (Rouder et al., 2012).

2) Analyze the data given the selected priors and models. Consider the BF and use the  $BF_{10}$  as evidence of how one should update their beliefs about the models.

Based on the flexibility of the analysis, the only assumption that needs to be made is that data exists such that two competing, plausible models with different constraints may be specified.

Bayesian inference improves upon the traditional frequentist point of view by allowing 214 not only a clear interpretation of the evidence provided by the data, but also the ability to 215 speak in favor of the null hypothesis. It is important to note that while previous work has 216 indicated that p-values and BF largely agree on which hypothesis should be supported, they 217 differ in the strength of that conclusion, especially when p-values were slightly lower than  $\alpha$ 218 (i.e., .05 to .01; Wetzels et al., 2011). However, some limitations do arise in this paradigm. 219 Bayesian analyses require the researcher to take an active role in the choice of prior 220 distributions for the phenomenon they are modeling, and this decision can take some effort 221 to fully understand; however, in the meantime, there are packages such as BayesFactor that 222 provide the researcher simple default options that can readily lend themselves to many 223 research areas with little fear of being outrageous specifications. Further, unlike NHST, 224 Bayesian analyses do not necessarily control long-run error rates, as the focus is on updating 225 current model beliefs. Another concern that many researchers have is that these analyses are 226 necessarily sensitive to prior choice. However, research has shown that the choice of priors has essentially no effect on conclusions when sufficient data has been collected as the priors 228 give way to the weight of the data (Klugkist & Hoijtink, 2007; Rouder et al., 2012) and when 220 reasonable priors are considered, data are only mildly sensitive to these (Haaf & Rouder, 2017). Finally, many believe Bayesian analysis to be too computationally intensive to 231 complete. However, many simple programs, packages, and tutorials exist to help ease the 232 transition from frequentist to Bayesian analysis (JASP Team, 2017; Kruschke, 2014; Morey 233 & Rouder, 2015). 234

### **Observation Oriented Modeling**

### 236 History

235

James Grice argues that our problems as a science go beyond use of NHST and extend into the philosophical ideas underpinning our research. Therefore, he developed a new paradigm called Observation Oriented Modeling (OOM, Grice, 2011, 2014; Grice, Barrett,

Schlimgen, & Abramson, 2012). He reasons that by viewing psychology through the lens of philosophical realism, instead of positivism, we should be able to properly and effectively 241 conduct research and analyze data. In contrast to positivism (i.e., which is solely concerned 242 with finding an effect, not with how the effect occurred), philosophical realism holds that the 243 causal structure of nature can be understood through scientific investigation. The goal is 244 then to understand the causal mechanisms that give rise to the patterns observed in a given 245 set of observations, which in here would refer to data. Switching to this philosophy allows for 246 techniques that match the daily activities of social scientists in their endeavors to unravel 247 the story of how humans operate. Using OOM, a researcher does not focus on population 248 parameters and the various assumptions underlying statistical tests (e.g., random sampling, 249 normality, homogeneity of population treatment differences, etc.). 250

Generally speaking, this approach can handle any type of data, including ordinal 251 rankings and frequency counts, as all analyses are calculated in the same general fashion (see 252 Valentine & Buchanan, 2013 for an example). This simplicity occurs because OOM works on 253 the deep structure of the data. Through observational definition, the program separates 254 these units into binary code. Deep structures can be arranged to form a matrix, which can 255 then be manipulated via matrix algebra, binary Procrustes rotation, and other operations to 256 investigate the data. The most important values from any OOM analysis are the PCC 257 (percent correct classification) values. These values represent the summation of how well an 258 individual's responses matched the stated or expected pattern or, in the case of causal 259 modeling, how many of the individual's conformed to a given cause. Complete matches are 260 the proportion of observations that match the researcher-designated pattern on all dimensions. For example, in a three-level Ordinal Pattern Analysis (OPA), a person would 262 be tallied as a "complete match" if the ordinal pattern of his/her data matched the expected ordinal pattern across all three levels. Imagine we have set a pattern that designates Time 1 264 < Time 2 < Time 3. For example, imagime we have data for two hypothetical individuals. 265 Person A has values of 3, 4, and 5 at timepoints 1, 2, and 3, respectively, while person B has

values of 4, 5, and 2. We can see that Person A matched the pattern completely, and 267 therefore would be counted in the PCC value. However, while person B matched the first 268 part of our pattern (time 1 less than time 2), they did not match on the third point of our 269 pattern (time 2 less than time 3); thus, they would not be counted in the PCC value. As the 270 PCC is simply the percentage of individuals in a sample whose responses match the expected 271 ordinal pattern perfectly, its computation is therefore not based on means or variances, but 272 on the basis of the observations themselves. The PCC value replaces all of the conventional 273 values for effect size used in statistical analyses. 274

The analysis we focus on here (OPA) does not form any type of linear or nonlinear 275 equation or regression, but simply looks for those individuals who match the expected 276 ordinal pattern (Grice, Craig, & Abramson, 2015). The main point of the analysis, then, is 277 to see how many people fit the expected pattern which is based on a causal theory. If all 278 causes are accounted for in the study and observations have been made with sufficient 279 precision and accuracy, then 100% of the persons should fit the expected pattern; otherwise, 280 a lower PCC value will be expected and it is up to the researcher to determine how high a 281 PCC must be in order to support an inference to the causal mechanism. 282

In OOM, traditional p-values are no longer utilized (Grice, 2011). As a secondary form 283 of reference value, a chance value (c-value) is obtained, which is a type of randomization test 284 in which the researcher determines the number of randomized trials for the test (e.g. 1,000 or 285 5,000 randomized versions of actual observations). This procedure is akin to permutation 286 tests, where PCCs are computed for the randomized data to form a distribution. The 287 observed PCC is then compared to these values, and the c-value (which is an empirical probability) is determined. If the randomized data sets fit the pattern as well as or better 289 than the actual data does, the c-value will be high (close to 1). Low c-values (close to 0) indicate a pattern of observations that is improbable (i.e., unlikely produced by chance) 291 when compared to randomized versions of the same data. Although low c-values, like low 292 p-values, are desirable, c-values do not adhere to a strict cut-off and should be considered a 293

294 secondary form of confirmation for the researcher that their results are distinct.

## 295 Typical Procedure

297

298

299

300

301

302

303

304

305

The OPA is analogous to repeated measures ANOVA and contains two steps.

1) Designate the expected ranked pattern: each variable as being higher, lower, or equal to the other variables. For instance, for our analyses we defined the following pattern of individual responses  $X_i$ , whereby the first time point should be less than the second time point which should be less than the third time point. This pattern can be operationalized as follows:

$$X_{i_1} < X_{i_2} < X_{i_3}$$

2) Analyze the data using the OPA. Consider the PCC (the percentage of individuals matching the ordinal hypothesis) and c-values in light of the data and use your best judgment as to whether or not the data conform to the expected pattern. This analysis only requires the assumption that the data exists such that a pattern may be designed.

As with all of these methodologies, limitations do exist. This approach is largely
concerned with patterns of responses, not with magnitudes of differences, which may be an
integral piece of information to some researchers. Unlike all approaches mentioned before, we
do not discuss the probability of some data given our hypothesis here, and instead focus on
the observed responses of the individual and how it may or may not behave as expected.
Finally, similar to the Bayesian analysis, long-run error rates are not discussed in this
methodology.

## A Simulation Study

### 4 Simulated Data

313

In this study, we generated 20,000 datasets by manipulating sample size and effect size 315 for a repeated measures design with three levels. A repeated measures design was chosen as 316 it is widely used across many disciplines of psychology. These datasets were created using the mvtnorm package in R (Genz et al., 2017), and all code for simulations can be found at 318 https://osf.io/u9hf4/. Interested readers can easily adapt the R code to incorporate different 319 research designs. Likert data, ranging from 1 to 7, was created by rounding mytnorm 320 estimates to whole numbers and truncating any data points out side of the appropriate range 321 (i.e. values < 1 were rounded to 1, and values > 7 were rounded to 7). We specifically chose 322 Likert-type data as this data type is one of the most common data types utilized by most 323 social scientists. Additionally, we add to the literature as other simulations have chosen to 324 use completely continuous data (i.e., simulated numbers are often precise to 10+ decimals, 325 which is unlikely for traditional sampling). The simulated data did increase in skew with this 326 procedure from approximately no skew (i.e., <0.01) to approximately 0.40 for the smallest 327 and no effect conditions; however, these values closely resembled a normal distribution with 328 the use of mytnorm. The population means for each level were set to 2.5, 3.0, and 3.5, and 320 pairwise effect sizes (e.g., the comparison between time 1 v. time 2 and time 2 v. time 3) 330 were manipulated by adjusting the standard deviation to create negligible effects (SD = 3.39, 331 d = 0.10), small effects (SD = 3.00, d = 0.20), medium effects (SD = 0.50, d = 0.50), and 332 large effects (SD = 0.10, d = 0.80) using Cohen (1992)'s traditional guidelines for d 333 interpretation. The smallest effect size was set such that Likert style data could still be retained with the smallest possible effect size. Sample size was manipulated at 10, 30, 100, 500, and 1,000 data points. All combinations of the five sample sizes and four effect sizes 336 were created, and each dataset was simulated 1,000 times, totaling 20,000 datasets. 337 The advantage of using mvtnorm and set SDs for each group was the ability to 338 approximate the assumptions of normality by randomly generating from a multivariate 339

normal distribution, and homogeneity by setting equal SDs for each group. In a repeated measures design, the assumption of sphericity was met by setting the correlations between levels in mvtnorm to zero. By maintaining the lowest level of relationship between levels, we additionally controlled for power and examined situations of significance given the lowest power scenario. During the data simulation, the standard deviation of the difference scores was examined to maintain differences greater than zero, especially for low N simulations.

## 346 Analyses Performed

Descriptive Statistics. Means, mean differences between levels, and the confidence intervals for each mean can be found in the complete dataset online, https://osf.io/u9hf4/. For each simulation, we also calculated d values using the standard deviation of the difference score as the denominator ( $d_z$ , Lakens, 2013). The MOTE library was used to calculate the non-central confidence interval for each d value as well (Buchanan, Valentine, & Scofield, 2017; Cumming, 2014). This data was mainly used to determine if simulations were meeting expected values overall.

Parametric NHST - Repeated Measures ANOVA. Repeated measures 354 ANOVA using the ezANOVA() function in the ez library was utilized with type three sum of 355 squares (Lawrence, 2017). This style of ANOVA is used to compare the same individuals 356 across multiple or all conditions in an experiment. The null hypothesis states that there are 357 no significant differences between population means, and the research hypothesis posts that 358 there are differences between some population means, but does not specify which population 359 means may differ, just that one or more will differ as the alternative. This test uses the F360 distribution focusing on p values. 361

To determine where differences may exist, post hoc dependent t-tests are normally analyzed in the event of a significant F-ratio. We did not run all pairwise comparisons, instead focusing on the linear trend simulated by comparing level one to two and level two to three. This set of comparisons also controlled the effect size between comparisons, as

comparing level one to three would have doubled the effect size. However, we assumed that 366 typical researchers might compare all three pairwise combinations in practice and used a 367 Bonferroni correction across all three possible pairwise combinations to calculate p values for 368 post hoc tests. Therefore, while we only discuss the two comparisons, we utilized the more 369 stringent cutoff of the Bonferroni correction as we believe this procedure would be how the 370 majority of researchers would handle the data. Interested readers can find all three 371 comparison values in the complete dataset online. Following traditional usage, a p-value of 372 less than .05 was binned as significant, whereas p-values ranging from .10 to .05 were binned 373 as marginally significant. Any p-values larger than .10 were binned as non-significant. A 374 second set of p-value comparisons was calculated given Benjamin et al. (2018)'s suggestion 375 to change  $\alpha$  criterion to less than .005. Any p-value less than .005 was binned as significant, 376 while data ranging from .005 to .10 was marginal or suggestive, and p > .10 was non-significant. 378

Bayesian Analysis: Bayes Factor. We compared a null model with one grand 379 mean for all three levels to an effects model wherein means were allowed to differ using the 380 BayesFactor package (Morey & Rouder, 2015). The default in this package is a Jeffreys prior 381 with a fixed rescale (0.5) and random rescale (1.0). BF were calculated, and follow up t-test 382 BFs were computed for the same two comparisons as in the previous models using default 383 priors from the BayesFactor package (e.g., Jeffreys prior for population variance, Cauchy 384 prior for standardized effect size). To compare Bayesian results to other statistical methods, 385 we used recommendations from (????) to bin results into weak evidence (BFs < 3), positive 386 evidence (e.g., akin to marginal p-values, BFs = 3-20), and strong evidence (BFs > 20). We must stress here that BF interpretation should focus on understanding the odds of model ratios, not necessarily the presence or absence of an effect. However, given that we wanted to 389 compare the conclusions one would reach given this data in a Bayesian paradigm to that of a 390 frequentist paradigm, these bins are used as a convenient comparison to the freughtist 391 procedures using set criteria for interpretation (Morey, 2015). Should any reader become 392

curious how a different set of binning values affect our analyses, all code and data are at their disposal at https://osf.io/u9hf4/.

**OOM:** Ordinal Pattern Analysis. An R script of the Ordinal Pattern Analysis 395 from Grice et al. (2015)'s OOM program was provided from Sauer and Luebke (2016). We set the expected ranked pattern as level one less than level two less than level three. Once 397 this pattern was defined, we then analyzed the data to see if each individual's set of observations matched this expected ordinal pattern. PCC values were generated, and c-values were computed by randomizing the data 1,000 times. Solely for purposes of 400 comparison, we used the following significance coding schema: significant studies had a high 401 PCC value (.50 < PCC < 1.00) and a low c-value (c < .05), marginal studies had a high 402 PCC value and a moderate c-value (.05 < c < .10), and non-significant studies had low PCC 403 values (PCC < .50), regardless of their c-values. Again, we must stress that this paradigm 404 eschews binning estimates and that our use of bins was a) discussed and decided upon before 405 data analysis, and b) created only for the purposes of comparing this new methodologies 406 possible conclusions to that of a frequentist framework. We welcome interested readers to 407 explore the data more, defining their own bins and viewing the affects, by viewing and 408 editing our code at https://osf.io/u9hf4/. 409

410 Results

### Percent of Estimates

For all simulations, we first binned the estimates into significant, marginal, and non-significant effect categories as described in the Analyses Performed section above. Next, we calculated the percentage of these analyses that would be classified into each of these categories, separated about by statistical analysis, sample size, and effect size. These estimates were binned across both the overall and follow up *post hoc* tests, and the combined data is presented for this analysis. Since all three categories of binning total to 100%, we present only the significant and non-significant results. All analyses and findings can be

found online at https://osf.io/u9hf4/. Significant critical omnibus estimates are presented in Figure 1. All figures discussed in this manuscript may be viewed as interactive graphics on our OSF page through a provided Shiny app. In Figures with sample size on the axes, we log transformed N to allow for visual distinction between sample sizes, as smaller N values were compressed when using the N = 10 to 1000 on the axis. Both N and  $\log(N)$  can be found in the Shiny app, along with the ability to zoom in to specific ranges of sample size.

For negligible effects at p < .05 (solid lines), we found that NSHT analyses showed a 425 predictable Type I error bias, in that they detected significant estimates with extremely 426 small d values as sample size increased. Binned BF values showed a similar pattern, but 427 were more conservative with less percent significant estimates. OOM analyses were the most 428 conservative, essentially never detecting an estimate in the negligible effect simulations. 429 Small effect sizes showed the same pattern for NHST, BF, and OOM results, with the 430 proportion of significant estimates increasing more rapidly and asymptoting at a smaller 431 sample size than negligible effects. At medium effect sizes, NHST analyses nearly always 432 detected significant estimates, while BF and OOM analyses would have been considered 433 significant around 75% of the time. Interestingly, with large effect sizes, OOM analyses 434 mirrored NHST by always detecting estimates, and BF analyses were generally more 435 conservative except at the largest sample size. Figure 1's dashed lines indicate the results if values were binned at p < .005, and the differences between these results were very subtle. 437 Lowering  $\alpha$  reduced the number of significant estimates at small N values for all four effect 438 sizes, with more pronounced differences at negligible and small effect sizes. However, the 439 graphs converged to the same conclusion that large enough sample sizes could produce significant results at negligible and small effect sizes. 441

Figure 2 portrays the results for non-significant binned simulations, which were the same for both  $\alpha$  criterion. Across all effect sizes, BF and NHST showed similar results, where non-significant estimates were detected at lower sample sizes for negligible and small effect size simulations. At medium and large effect sizes, almost all estimates would have

been considered significant, therefore, detection rates for non-significant estimates were
around zero. OOM displayed a conservative set of findings, showing nearly 100%
non-significant estimates at negligible and small effect sizes (mirroring results from Figure 1).
At medium effect sizes, approximately a quarter of estimates were non-significant,
illustrating the conservative nature of OOM interpretations.

# 51 Percent Agreement

A goal of this project was to expand the toolbox of options for researchers to determine 452 what evidence supports their hypotheses by examining multiple methodologies. We 453 calculated the percent of time that all analyses agreed across overall and post hoc comparison 454 estimates. Figure 4 illustrates the pattern of 100% agreement on effects for critical omnibus 455 tests only at each sample size and effect size. Figure 5 portrays the results for post hoc tests, 456 which only uses NHST and Bayes Factor analyses, as OOM does not have a post hoc test 457 (i.e., the test is a pattern analysis that presupposes the expected direction of post hoc tests). 458 When effect sizes were negligible and for small effects, agreement was best across small 459 samples and decreased across sample size, as NHST was overly biased to report significant 460 estimates and OOM and BF were less likely to do so. For medium and large effect sizes, 461 50-75% agreement was found, usually regardless of sample size. Additionally, we found that 462 for negligible, small, and medium effects, agreement for post hoc tests was higher than 463 agreement for overall comparisons. The post hoc comparisons for levels 1 to 2 and levels 2 to 464 3 were less likely to be binned as significant across negligible and small effects, so the 465 agreement levels were higher for these individual comparisons due to non-significant follow up tests. The critical omnibus test was more likely to be significant due to the inclusion of effect of comparisons between level 1 and 3, which were double the effect size. However, these post hoc comparisons do not include the conservative significant binning from OOM, 469 which decreased critical omnibus 100% agreement seen in Figure 4. Again, the differences 470 between p < .05 and p < .005 were minimal. Complete tables of percentages of binning

across critical omnibus and post hoc tests, along with agreement percentages broken down by 472 bins can be found at https://osf.io/u9hf4/. 473

### Criterion Comparison

475

As the relationship between BF and p-values is already well documented, we will not discuss them here beyond stating that we found the expected pattern shown in previous 476 work (Rouder et al., 2012), and that individuals who wish to view this comparison, as well as 477 all the other comparisons discussed here should visit our interactive Shiny application at our 478 OSF page. Of interest was the comparison of OOM indices to traditional NHST and 470 Bayesian indices. First, in Figure 6, PCC values are plotted against log BF values and 480 p-values. The log of BF was taken to include all values on a viewable axis, and all infinity 481 values were windsorized to the next highest point. Increasing sample size is shown by 482 increasing point size and lighter colors. Additionally, since OOM values are a combination of 483 PCC and c-values, c-values below .05 are shown as Xs instead of dots. Therefore, all values 484 PCC >= .50 that are also denoted as Xs would be considered significant in this example. 485 The provided Shiny application uses color to distinguish sample size differences, as well as includes options to create each combination effect size and criterion individually. Only two 487 graphs are provided here to save space. 488 In Figure 6, the left hand column portrays the relationship between log BF values and 480 PCC values in negligible and medium effect sizes. With negligible effect sizes, we found large 490 variability in PCC values across a small span of BF values while sample sizes remained low, 491 but as N increased, we saw that the range of PCC values narrowed considerably with increasing BF values. Therefore, as sample size increased, the PCC values constricted, while BF values expanded. A similar pattern appeared when viewing the medium sample size graph, as again PCC values became less variable with increased sample size, and BF tended to increase both in variability and in value as the sample size grew. Here, we can see a 496 benefit of PCC, along with c-values, as increasing sample size portrayed more precision in

PCC, instead of the increased variability found in BF.

It is also important to note that within the negligible effects graph, while many of 499 these PCC values reached high values, that these values did not denote patterns that would 500 necessarily be seen as unique. c-values were a secondary measure of evaluation that 501 eliminated a number of these matches from being considered meaningful. A large majority of 502 points with larger sample sizes on the figure included low chance values, however, the PCC 503 values for these simulations were lower than a meaningful percent used for cutoff criterion. 504 This two-step process helped to weed out effects that were negligible, especially at larger 505 sample sizes. 506

Additionally, we compared p-values and PCC values, which are illustrated on the right 507 hand side of Figure 6. Again, PCC values showed far more variability with small sample 508 sizes, and the p-values associated with these smaller sample sizes were also quite variable. 509 Importantly, even when an effect was negligible, PCC values become less variable with 510 increasing sample size. PCC values also indicated that there was little evidence of the 511 hypothesized pattern by shifting toward zero. p-values decreased in variability at high 512 sample sizes and shifted toward minuscule values, thus, pointing toward rejecting the null 513 hypothesis. With medium effect sizes, both p-values and PCC values were variable at small 514 sample sizes. At larger sample sizes, p-values decreased towards floor effects (i.e. closer to 515 zero), while PCC values simply narrowed in range shifting slight above .50. The benefit of 516 multiple criteria evaluation here was clear, as p-values increasingly indicated significance as 517 sample size increased, PCC values were not effected in this way and thus presented a more 518 stable picture of the presence of an effect. While multiple criteria may not completely reduce the interpretation of false positives in the literature, the relationship between these values illustrated that multiple indices can provided a clearer picture of the evidentiary value available in a study. CLARIFY HERE THAT WE'RE NOT SAYING TO USE ALL THESE 522 AT THE SAME TIME, BUT THAT RESEARCHERS SHOULD CONSIDER THAT THEY 523 HAVE MULTIPLE OPTIONS AND KNOW THE BENEFITS, DRAWBACKS, AND HOW

EACH COMPARE.

526 Limitations

Within any study a number of limitations exist. The largest limitation of our study is 527 that we chose to focus on a simple three level repeated measures ANOVA design. The benefit 528 to this focus is the simplicity of understanding the relationship between analyses, while also 529 using a well understood NHST procedure. However, is possible that these same relationships 530 (CLARIFY THAT THE RELATIONSHIPS WE ARE TALKING ABOUT ARE HOW 531 THESE 3 METHODS ARE SIMILAR/DIFFERENT/AGREE/DISAGREE) may or may not exist in alternative design contexts. Additionally, our choices for classification of significant effects for p-values, BF, PCC, and c-values was based on what we believe a reasonable researcher may designate; however, these classifications may vary in the real world. We 535 provide open access to our simulations and code so that an interested party can tinker with 536 these choices. We believe the global conclusions would likely be similar across changes, 537 however, the specific percentages and patterns would likely differ. Finally, due to the 538 specification of our simulation we did not violate any statistical assumptions. It is possible 539 that the violation of these assumptions may cause changes in the relationships we see here. 540

Discussion

This manuscript was designed to showcase two alternative paradigms to NHST researchers and to compare the conclusions these alternative methodologies might make in a given data environment to those NHST would make. We believe that the awareness of multiple methodologies might assist in strengthening our conclusions and improving reproducibility by giving researchers the ability to identify an optimal method given the question at hand. Further, we believe that should a researcher utilize multiple methodologies (e.g., analyzing and reporting both a NHST p-value as well as an OOM PCC value) that these estimates in tandem can help readers to weight these various forms of evidence and arrive at a more robust conclusion. We found that changing the threshold at which p-values

are deemed significant had little to no effect on conclusions, especially at large sample sizes, 551 regardless of effect size. This finding is notable as the article by Benjamin et al. (2018) 552 states that an increase in sample size is likely to decrease false positives "by factors greater 553 than two" (p. 10), and work by Pericchi and Pereira (2016) state that an adaptive level of 554 significance would be beneficial in these circumstances—neither of which are not supported 555 by our simulations. Our science will not grow by moving the significance line in the sand, as 556 this line has already been shown to have "no ontological basis" (Rosnow & Rosenthal, 1989, 557 p. 1277). 558

Instead, we need to embrace the multitude of perspectives available to us and to begin 559 to employ these diverse approaches. While NHST can still serve us well when properly 560 utilized, it is important for researchers understand that different methods seek to answer 561 different questions, and that we need to ensure that we are using the right method to answer 562 a given question. When evaluating evidence in order to answer these questions we must be 563 wary of looking for significant differences and focus instead to find meaningful differences. 564 By combining these approaches we may be better able to qualify the strength of our evidence 565 and discuss a more nuanced version of our data. Additionally, while all of these methods have drawbacks, when taken combined these methods can begin to overcome many of these limitations. For instance, given a large sample size, we would expect BF values to be very large and p-values to be very small, both indicating that the null model/hypothesis should not be supported. However, if we also have a PCC value of .30, we may decide that it is 570 possible that this effect is very small and possibly negligible. This multifaceted approach 571 may help to curb our enthusiasm over small or negligible "significant" effects that may not 572 be practically meaningful and possibly may not replicate. Regardless if analyses agree or 573 disagree on the presence of an effect, a researcher can investigate the size of the effect and 574 discuss conclusions accordingly. Each methodology behaves slightly differently in given data 575 environments, which might begin to highlight meaningful differences when discussed together. 576

Some may contest that all of these analyses are capable of being hacked, like p-values,

577

through researcher degrees of freedom, choice of priors, or pattern choice, among other 578 actions (Simmons et al., 2011). Transparency throughout the research process is key to 579 eliminating these issues, as  $\alpha$  changes may only encourage bad research practices with the 580 current incentive structure on publishing. Although we have the capability to share research 581 across the world, research often still occurs behind closed doors. The Open Science 582 Framework grants insight into research processes, allowing researchers to share their 583 methodologies, code, design, and other important components of their projects. In addition 584 to posting materials for projects, pre-registration of hypotheses and methodology will be an 585 important facet in scientific accountability. Further, with increased transparency editors and 586 other researchers can weigh the evidence presented according to their own beliefs. 587

Our key suggestion in this project is the redefinition of evidentiary value. The current 588 focus on p-values has shown to be problematic, as many of the studies from the Open Science 580 Collaboration (2015) do not replicate at p < .05 or p < .005 (Lakens et al., 2018). With the 590 change in transparency mentioned above, publishing research with solid research designs and 591 statistics, regardless of p-values, will allow for a broader range of evidence to become 592 available. Publishing null findings is critical in replication and extension for discovering the 593 limits and settings necessary for phenomena. Registered replications and reports will allow studies to be accepted prior to results being known, thus allowing researchers to focus on experimental design and hypotheses apriori instead of p-values post hoc. Reports should 596 describe multiple indicators of evidence, such as effect sizes, confidence intervals, power 597 analyses, Bayes Factors, and other descriptive statistics (Finkel, Eastwick, & Reis, 2015; 598 Nosek & Lakens, 2014; van 't Veer, Giner-Sorolla, Van't Veer, & Giner-Sorolla, 2016).

A misunderstanding of statistical power still plagues psychological sciences (Bakker,
Hartgerink, Wicherts, & Maas, 2016), and the effect of sample size, especially small ones,
was shown here by comparing the criterion available in these analyses. Often, individual
research labs may not have the means to adequately power a proposed study. Multilab
studies and collaboration with other scientists is fundamental to alleviating these issues,

while encouraging interdisciplinary science. Collaboration increases our statistical abilities, 605 as every researcher cannot be expected to be proficient in all methods and analyses, but 606 teams of researchers can be assembled to cover a wider range of statistical skills to provide 607 adequate estimates of evidence in their reports. We understand that there may be resistance 608 to the implementation of multiple methodologies as these new methodologies take time and 609 effort to learn. However, through the use of free programs (JASP, R, OOM, Shiny) and 610 tutorials (YouTube, Coursera, http://www.statstools.com), we believe all researchers are 611 capable of learning these analyses. We believe that through the expansion of our analytical 612 knowledge and application of these new methodologies, we can begin to attenuate some of 613 the strain currently placed on psychological science and to increase the strength of evidence 614 in our discipline. 615

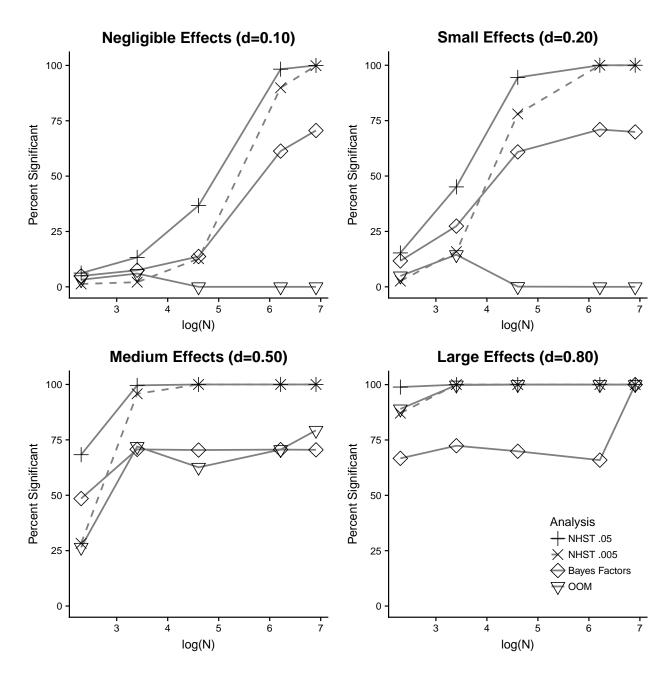

Figure 1. For NHST analyses only, percent of significant estimates at p < .05 (solid) and p < .005 (dashed) for each analysis given effect size and sample size.

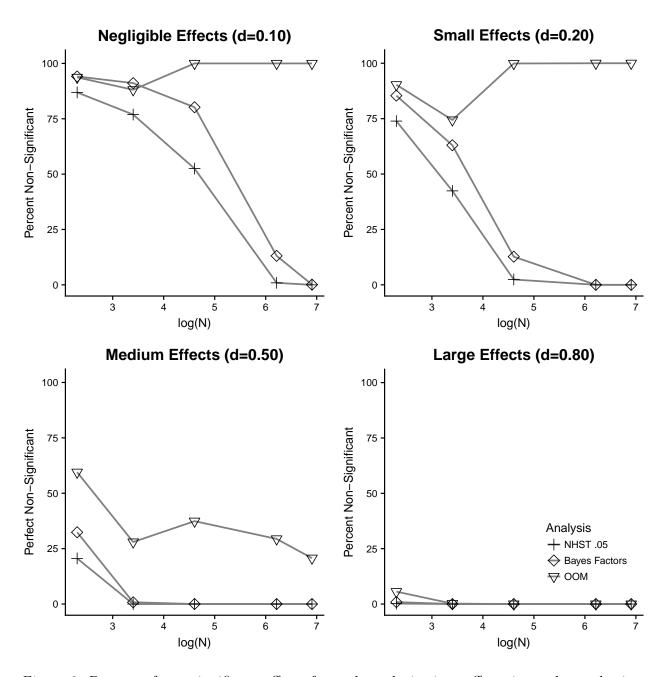

Figure 2. Percent of non-significant effects for each analysis given effect size and sample size.

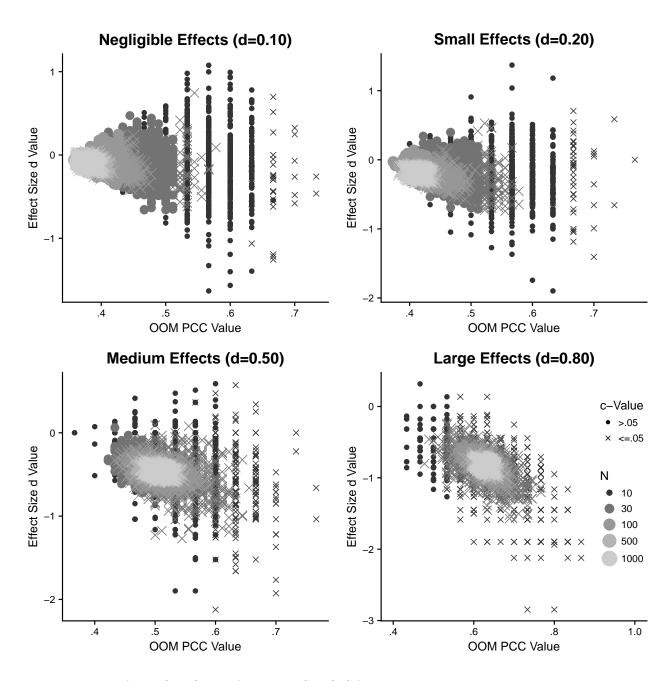

Figure 3. WHAT DO YOU WANT THIS TO SAY

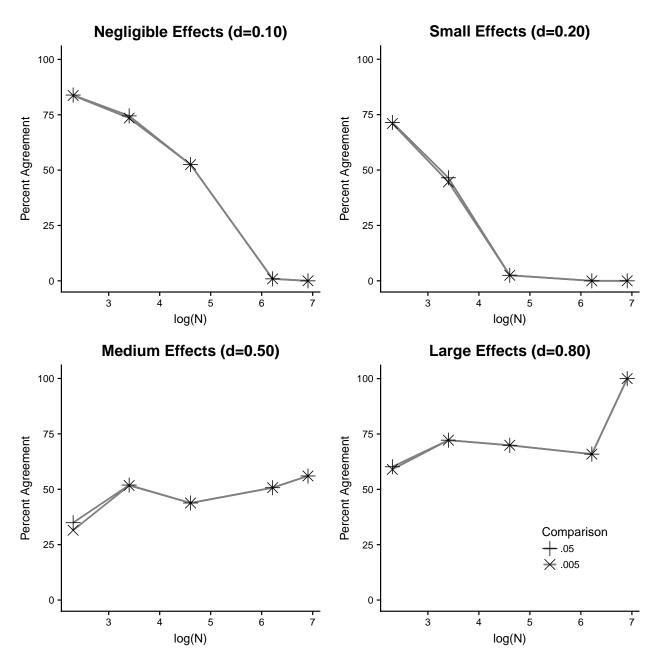

Figure 4. Percent of agreement across all analyses given effect size and sample size for omnnibus tests.

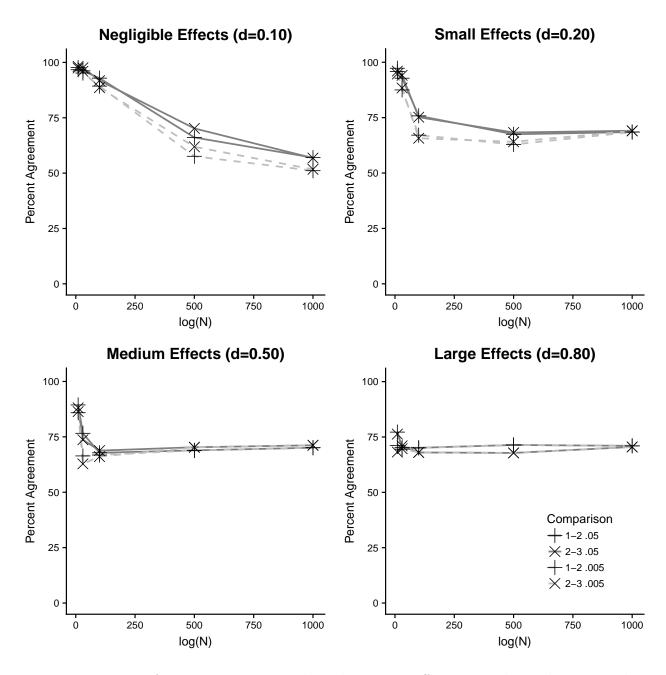

Figure 5. Percent of agreement across each analysis given effect size and sample size posthoc tests with p < .05 (solid) and p < .005 (dashed). Note that this graph only compares the NHST and BF conclusions.

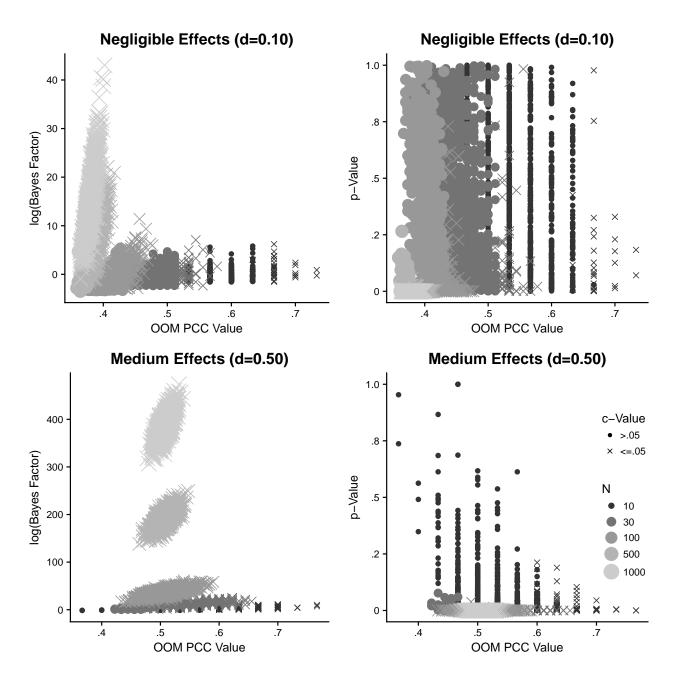

Figure 6. PCC and c-values plotted against p and BF values for negligible and medium effect size conditions. Xs indicate simulations with c-values < .05,which were binned as significant if they were found in conjunction with PCC values over .50. Point size and color indicates sample size wherein larger samples are lighter colors. Please note that the key for the entire set of graphics is in the bottom right hand corner.
