Abstract

Modeling, evidence

Null hypothesis significance testing is frequently cited as a threat to the validity and 18 reproducibility of the social sciences. While many individuals suggest we should focus on 19 altering the p-value at which we deem an effect significant, we believe this suggestion is 20 short-sighted. Alternative procedures (i.e., Bayesian analyses and Observation Oriented 21 Modeling; OOM) can be more powerful and meaningful to our discipline. However, these 22 methodologies are less frequently utilized and are rarely discussed in combination with 23 NHST. Herein, we discuss the historical roots, procedures, and assumptions of three 24 methodologies (NHST, Bayesian Model comparison, and OOM), then compare the possible 25 interpretations of three analyses (ANOVA, Bayes Factor, and an Ordinal Pattern Analysis) in various data environments using a simulation study. The simulation generated 20,000 unique datasets which varied sample size (Ns of 10, 30, 100, 500, 1,000), and effect sizes (ds of 0.10, 0.20, 0.50, 0.80). Through this simulation, we find that changing the threshold at which p-values are considered significant has little to no effect on conclusions. Further, we find that evaluating multiple estimates as evidence of an effect can allow for a more robust and nuanced report of findings. These findings suggest the need to redefine evidentiary value 32 and reporting practices. 33 Keywords: null hypothesis testing, p-values, Bayes Factors, Observation Oriented 34

3

Beyond p-values: Utilizing Multiple Methods to Evaluate Evidence

36

Recent events in psychological science have prompted concerns within the discipline 37 regarding research practices and ultimately the validity and reproducibility of published 38 reports (Etz & Vandekerckhove, 2016; Lindsay, 2015; Open Science Collaboration, 2015; van 39 Elk et al., 2015). One often discussed matter is over-reliance, abuse, and potential hacking of p-values produced by frequentist null hypothesis significance testing (NHST), as well 41 misinterpretations of NHST results (Gigerenzer, 2004; J. P. A. Ioannidis, 2005; Simmons, Nelson, & Simonsohn, 2011). We agree with these concerns and believe that many before us have voiced sound, generally accepted opinions on potential remedies, such as an increased focus on effect sizes (Cumming, 2008; Lakens, 2013; S. E. Maxwell, Lau, & Howard, 2015; B. A. Nosek, Spies, & Motyl, 2012). However, other suggestions have been met with less enthusiasm, including a recent article by Benjamin et al. (2018) advocating that researchers should begin thinking only of p-values less than .005 as "statistically significant", thus changing α levels to control Type I error rates. Additionally, Pericchi and Pereira (2016) promote the use of fluctuating α levels as a function of sample size to assist with these errors. We argue it is not the p-value that needs to be rethought when seeking evidence, but rather what that p-value can tell you in relation to other indicators. While NHST and p-values may have merit, researchers have a wealth of other statistical tools available to them. We believe 53 that improvements may be made to the sciences as a whole when individuals become aware of the tools available to them and how these methods may be used in combination to 55 strengthen understanding and conclusions. These sentiments have been shared by the American Statistical Association who recently held a conference focusing on going beyond 57 NHST, expanding their previous stance on p-values (Wasserstein & Lazar, 2016). 58 Therefore, we undertook this project to begin to let researchers see the similarities and differences both within the methodological design, as well as within the interpretations of statistics as meaningful. Herein, we have chosen three methodologies to focus on: NHST, 61 Bayes Factor comparisons, and Observation Oriented Modeling. These three approaches will

be compared via simulated data using a repeated measures design with a Likert-type scale as the outcome variable. The aims of this study will be to discuss the conclusions that these three methods would make given the same data, and to compare how often these methodologies agree within different data environments (i.e. given different sample sizes and effect sizes). We hope that by discussing these methodologies in terms of a simple statistical analysis researchers will be able to easily compare and contrast methodologies. For this discussion, it is important to understand their historical background, procedural steps, and limitations, which are outlined below. After this discussion, we describe a simulation study comparing methodologies and α criteria, and end with a potential implications for researchers.

Null Hypothesis Significance Testing

74 History

73

88

Many attribute the frequentist NHST procedure to Ronald A. Fisher (Fisher, 1932). 75 However, Fisher's ideas are a far cry from the NHST procedure implemented today. Fisher 76 believed in creating one "null" hypothesis, which he described as a hypothesis to be 77 "nullified", or shown incorrect, not as a zero-difference hypothesis (Lehmann, 2011). He also believed that the use of any omnibus level of significance showed a "lack of statistical thinking" (Gigerenzer, Krauss, & Vitouch, 2004). He instead believed we should report the exact significance value of a test and let others make their own decision about the claims, 81 which is more in line with the typical reporting recommendations provided by the American Psychological Association (American Psychological Association, 2010). Fisher spoke of this work to William Gosset, the man who created the Student's t-test and contributed work on the correlation coefficient (Lehmann, 2011). Gosset in turn discussed the idea of an alternative hypothesis, a piece not included in Fisher's procedure, with decision theorist Egon Pearson.

From this discussion, Egon Pearson and Jerzy Neyman created Neyman-Pearson

decision theory. This theory consists of two hypotheses (i.e., null and alternative) and a binary decision criteria (i.e., significant or not, Lehmann, 1993). However, this procedure created the possibility of researcher decision errors (Dienes, 2008). A researcher may falsely 91 reject the null hypothesis (Type I error, α) or falsely fail to reject the null (Type II error, β). 92 α levels set the binary decision criteria, which are used as the critical p-value for hypothesis 93 testing (i.e., p < .05), and are thus seen as evidence to reject the null hypothesis. β and power are inherently linked, as the likelihood of finding a true effect increases when beta 95 decreases (S. E. Maxwell & Delaney, 2004). Although α values can be chosen to be quite small, and methods can decrease β values as well, a researcher can never know if they have 97 made the correct decision, or a decision error. Thus, Neyman and Pearson clearly state that a hypothesis should not be blindly supported based solely on the estimates of one statistical test, and that replication and reproduction of results are imperative. The recent work of the Open Science Collaboration (2015) has also highlighted the need for replication studies and 101 interpretation of results in an appropriate context. Additionally, Neyman and Pearson 102 emphasized that use of set α s and β s is illogical and sought instead for researchers to adjust 103 their analysis to the needs of the particular task at hand (Gigerenzer, 2004). 104

105 Typical NHST Procedure

Neither Fisher's hypothesis testing, nor Neyman-Pearson decision theory quite match
the NSHT procedure as it is taught and applied today. Psychologists have largely adopted
an amalgamation of the two approaches. Here, we attempt to outline what we believe is the
most appropriate way to carry out the traditional NHST procedure, although we note that
this set of steps is not necessarily how researchers carry out the procedure in practice:

1) Create two hypotheses, one to be "nullified" and one "alternative" hypothesis. Within
this repeated measures framework, most researchers would define a null hypothesis $(H_0) \text{ that indicates of all three time points are equal. The alternative hypothesis } (H_A)$ would then be that the means of all three time points are not equal in some form.

These can be operationalized in our example data as follows:

115

119

120

121

122

123

$$H_0: \mu_1 = \mu_2 = \mu_3$$

$$H_A: \mu_1 \neq \mu_2 \neq \mu_3$$

¹¹⁶ 2) Select an α level that is appropriate given the context of your research, your analysis plan, ¹¹⁷ and your research question, and do not blindly adopt an omnibus critical p-value (Lakens et ¹¹⁸ al., accepted).

3) Compute your given analysis and identify the corresponding p-value. If your p-value is less than the chosen α , reject the null hypothesis and state that there appear to be differences between your means; however, if your p-value is greater than or equal to the value selected, do not reject the null hypothesis, and state that a difference between the means could not be supported.

While the NHST procedure itself gives us testable models, the specific analysis used to 124 test these models here, the repeated measures ANOVA with 3 levels, requires some 125 additional assumptions that must be met before an analysis is begun (Tabachnick & Fidell, 126 2012). Data need to have no missing values and no outlying or influential observations. Data 127 must have a normal sampling distribution, be linearly related, and have independent errors. 128 Depending on the statistical test, data must also be checked for equal variances, sphericity, 129 and additivity. These assumptions can be checked and, if necessary, corrected for; however, 130 violations of these assumptions can lead to inaccurate decisions and attenuated power. 131

While this approach is widely used, there are many limitations associated with it.

First, this method can be sensitive to violations of the stated assumptions, and especially, if
the sample size is not large enough to create a normal sampling distribution (Tabachnick &
Fidell, 2012). Even if assumptions are met, or nonparametric tests are implemented, this
methodology does not allow a researcher to state anything about the absence of an effect
(i.e., no true differences). Through traditional NHST, one can only discuss evidence

regarding the alternative hypothesis; one can never support the null hypothesis through this procedure. Given the recent findings regarding reproducibility, showing support for the absence of an effect is even more crucial (Bakker, van Dijk, & Wicherts, 2012; Lakens, 2017).

Bayes Factors

142 History

141

Thomas Bayes was a statistician and Presbyterian minister whose works are still 143 influential today (Bellhouse, 2004). Bayes' theorem solved the inverse probability problem, namely that through the frequentist approach, one can only know the probability of data existing given a hypothesis being true, never the probability of a hypothesis being true given that the data exist (Dienes, 2008). Bayes' theorem allows one to calculate the probability of 147 a hypothesis given some data (posterior belief) by using how probable one believes the hypothesis to be before data was collected (prior belief) and how probable one believes the 149 data to be given one's hypothesis (likelihood). Thus, with his theorem, researchers are able 150 to update (through the use of the likelihood) our initial beliefs (our prior) given some data 151 (Gelman, Carlin, Stern, & Rubin, 2013). Pierre-Simon Laplace pioneered Bayesianism and 152 advocated for a broader interpretation of this theorem (de Laplace, 1774). The use of 153 Bayesian statistics has been suggested as an NHST alternative (Dienes, 2014; Wagenmakers, 154 2007), but this approach has largely been undervalued in favor of frequentist methods as, 155 until recently, Bayesian analysis required considerable computational effort. However, today 156 we possess the technology necessary to conduct Bayesian analyses efficiently. While open 157 source software, such as R and JASP, require minimal learning to be able to effectively 158 operated (Morey & Rouder, 2015), researchers will need to invest more effort to 159 understanding the focus and interpretation of Bayes Factor (BF) comparisons as they differ 160 from traditional NHST. 161

The Bayesian framework can be viewed as a continuum, with objective Bayesian analyses on one end, and subjective Bayesian analyses on the other (Press, 2002). While this

topic could lend itself to its own manuscript, here we will simply summarize the two 164 endpoints, and discuss where our analysis may be perceived to fall on the line. Objective 165 Bayesian analysis is closest to frequentist theory, as priors are set to be as uninformative as 166 possible to allow little, if any, influence on the estimates and distribution of the posterior; 167 thus, the data is allowed to maximally effect the posterior distribution. On the other end, 168 subjective Bayes analyses include rigorously informed priors so that current knowledge can 169 play a large role in the posterior. Our current analysis splits these two; we do not utilize 170 completely uniformed (objective) priors, as we can adjust for basic knowledge of the 171 constraints of our data type. Given the usual lack of information about underlying 172 distributions, a wider band of inclusion was used for prior information. The BayesFactor 173 package (Morey & Rouder, 2015) assists greatly in the choice of prior and is especially 174 user-friendly for applied researchers, as it makes use of recommended default priors that have been chosen to be safe to assume under a broad range of data and topics (Rouder, Morey, 176 Speckman, & Province, 2012; Rouder, Speckman, Sun, Morey, & Iverson, 2009). Instead of 177 conventional F, t, and p-values, a ratio of the likelihood of the alternative model to the null 178 is report, usually BF_{10} . For instance, $BF_{10} = 20$ would indicate that the effects model is 179 favored 20 to 1 over the null model. Conversely, if the BF_{10} were 0.10, the null model is 180 favored 10 to 1 over the effects model. 181

182 Typical Procedure

183

184

185

186

187

188

189

The procedure behind BF comparisons requires two steps.

1) One must design two models for the data. For our purposes, the first of these models will be the null model, which states that there are no differences between means (μ ; i.e. all of our observed values X_i , regardless of which time point they were assessed at X_{ij} , arise from a normal distribution N with some mean μ and variance σ^2). The second model for these analyses is the effects model, which states that each mean (μ) is allowed to be different from the grand mean by some amount (α ; as we now have

observations being drawn from three potential normal distributions, all of which may have a different mean value, but the same variance). These can be operationalized as follows:

$$H_0: X_{ij} \sim N(\mu, \sigma^2)$$

$$H_A: X_{ij} \sim N(\mu + \alpha_i, \sigma^2)$$

In designing these models, one must choose the prior distributions that are believed to
describe the data. Reasonable expectancies of where the data lie should be incorporated in
this decision based on previous research into the studied phenomena (Rouder et al., 2012).

Analyze the data given the selected priors and models. Consider the BF and use the BF_{10} as evidence of how one should update their beliefs about the models.

Based on the flexibility of the analysis, the only assumption that needs to be made is
that data exists such that two competing, plausible models with different constraints may be
specified.

Bayesian inference improves upon the traditional frequentist point of view by allowing 201 not only a clear interpretation of the evidence provided by the data, but also the ability to 202 speak in favor of the null hypothesis. It is important to note that while previous work has 203 indicated that p-values and BF largely agree on which hypothesis should be supported, they 204 differ in the strength of that conclusion, especially when p-values were slightly lower than α 205 (i.e., .05 to .01; Wetzels et al., 2011). However, some limitations do arise in this paradigm. 206 Bayesian analyses require the researcher to take an active role in the choice of prior distributions for the phenomenon they are modeling, and this decision can take some effort to fully understand; however, in the meantime, there are packages such as BayesFactor that allow the researcher simple default options that can readily lend themselves to many research 210 areas with little fear of being outrageous specifications. Further, unlike NHST, Bayesian 211 analyses do not necessarily control long-run error rates, as the focus is on updating current 212

model beliefs. Another concern that many researchers have is that these analyses are 213 necessarily sensitive to prior choice. However, research has shown that the choice of priors 214 has essentially no effect on conclusions when sufficient data has been collected as the priors 215 give way to the weight of the data (Klugkist & Hoijtink, 2007; Rouder et al., 2012) and when 216 reasonable priors are considered, data are only mildly sensitive to these (Haaf & Rouder, 217 2017). Finally, many believe Bayesian analysis to be too computationally intensive to 218 complete. However, many simple programs, packages, and tutorials exist to help ease the 219 transition from frequentist to Bayesian analysis (JASP Team, 2017; Kruschke, 2014; Morey 220 & Rouder, 2015). 221

Observation Oriented Modeling

223 History

222

James Grice argues that our problems as a science go beyond use of NHST and extend 224 into the philosophical ideas underpinning our research. Therefore, he developed a new 225 paradigm called Observation Oriented Modeling (OOM, Grice, 2011, 2014; Grice, Barrett, 226 Schlimgen, & Abramson, 2012). He reasons that by viewing psychology through the lens of 227 realism, instead of positivism, we should be able to properly and effectively conduct research 228 and analyze data. In contrast to positivism (i.e., which is solely concerned with finding an 229 effect, not with how the effect occurred), realism is the belief that effects conform to their 230 cause and that given the correct models of these processes we can begin to understand our 231 reality. By viewing science as knowing nature through its causes, we can use Aristotle's four 232 causes (material, efficient, formal, and final) to think in terms of structures and processes in order to explain phenomena. Switching to this philosophy allows for techniques that match the daily activities of social scientists in their endeavors to unravel the story of how humans operate. Using OOM, a researcher does not focus on population parameters and the various 236 assumptions underlying statistical tests (e.g., random sampling, normality, homogeneity of 237 population treatment differences, etc.). Instead, the researcher alternatively focuses on 238

observations at the level of the individual.

Generally speaking, this approach can handle any type of data, including ordinal 240 rankings and frequency counts, as all analyses are calculated in the same general fashion (see Valentine & Buchanan, 2013 for an example). This simplicity occurs because OOM works on 242 the deep structure of the data. Through observational definition, the program separates 243 these units into binary code. Deep structures can be arranged to form a matrix, which can then be manipulated via matrix algebra, binary Procrustes rotation, and other operations to 245 investigate the data. The most important values from any OOM analysis are the PCC 246 (percent correct classification) values. These values represent the summation of how well an 247 individual's responses matched the stated or expected pattern or, in the case of causal 248 modeling, how many of the individual's conformed to a given cause. Complete matches are 240 the proportion of observations that match the researcher-designated pattern on all 250 dimensions. For example, in a three-level Ordinal Pattern Analysis (OPA), a person would 251 be tallied as a "complete match" if the ordinal pattern of his/her data matched the expected 252 ordinal pattern across all three levels. Imagine we have set a pattern that designates that 253 time 1 responses should be less than time 2 which should be less than time 3. Given the data 254 for two hypothetical individuals in Table 1, we can see that person A matched the pattern completely, and therefore would be counted in the PCC value. However, while person B matched the first part of our pattern (time 1 less than time 2), they did not match on the third point of our pattern (time 2 less than time 3); thus, they would not be counted in the PCC value. The PCC value replaces all of the conventional values for effect size used in 250 statistical analyses.

The analysis we focus on here (OPA) does not form any type of linear or nonlinear equation or regression, but simply looks for those individuals who match the expected ordinal pattern (Grice, Craig, & Abramson, 2015). The main point of the analysis, then, is to see how many people fit the expected pattern which is based on a causal theory. If all causes are accounted for in the study and observations have been made with sufficient

precision and accuracy, then 100% of the persons should fit the expected pattern; otherwise, a lower PCC value will be expected and it is up to the researcher to determine how high a PCC must be in order to support an inference to the causal mechanism.

In OOM, p-values are no longer utilized (Grice, 2011). As a secondary form of 269 reference value, a chance value (c-value) is obtained, which is a type of randomization test in 270 which the researcher determines the number of randomized trials for the test (e.g. 1,000 or 271 5,000 randomized versions of actual observations). This procedure is akin to permutation 272 tests, where the original data is shuffled a number of times to create comparable data sets. 273 These randomized data sets are then compared to the designated pattern. If the randomized 274 data sets fit the pattern as well as or better than the actual data does, the c-value will be 275 high (close to 1). Low c-values (close to 0) indicate a pattern of observations that is 276 improbable (i.e., unlikely produced by chance) when compared to randomized versions of the same data. Although low c-values, like low p-values, are desirable, c-values do not adhere to 278 a strict cut-off and should be considered a secondary form of confirmation for the researcher 279 that their results are distinct. 280

281 Typical Procedure

282

283

284

285

286

287

288

289

The OPA is analogous to repeated measures ANOVA and contains two steps.

1) Designate the expected ranked pattern: each variable as being higher, lower, or equal to the other variables. For instance, for our analyses we defined the following pattern of individual responses X_i , whereby the first time point should be less than the second time point which should be less than the third time point. This pattern can be operationalized as follows:

$$X_{i_1} < X_{i_2} < X_{i_3}$$

2) Analyze the data using the OPA. Consider the PCC and c-values in light of the data and use your best judgment as to whether or not the data conform to the expected

pattern. This analysis only requires the assumption that the data exists such that a pattern may be designed.

As with all of these methodologies, limitations do exist. This approach is largely
concerned with patterns of responses, not with magnitudes of differences, which may be an
integral piece of information to some researchers. Unlike all approaches mentioned before, we
do not discuss the probability of some data given our hypothesis here, and instead focus on
the observed responses of the individual and how it may or may not behave as expected.
Finally, similar to the Bayesian analysis, long-run error rates are not discussed in this
methodology.

A Simulation Study

300 Simulated Data

290

In this study, we generated 20,000 datasets by manipulating sample size and effect size 301 for a repeated measures design with three levels. A repeated measures design was chosen as 302 it is widely used across many disciplines of psychology. These datasets were created using 303 the mytnorm package in R (Genz et al., 2017), and all code for simulations can be found at 304 https://osf.io/u9hf4/. Interested readers can easily adapt the R code to incorporate different 305 research designs. Likert data, ranging from 1 to 7, was created by rounding mytnorm 306 estimates to whole numbers and truncating any data points out the appropriate range 307 (i.e. values < 1 were rounded to 1, and values > 7 were rounded to 7). We specifically chose 308 Likert-type data as this data type is one of the most common data types utilized by most 309 social scientists. Additionally we add to the literature as other simulations have chosen to use completely continuous data (i.e., simulated numbers are often precise to 10+ decimals, 311 which is unlikely for traditional sampling). The population means for each level were set to 312 2.5, 3.0, and 3.5, and effect sizes were manipulated by adjusting the standard deviation to 313 create negligible effects (SD = 3.39, d = 0.10), small effects (SD = 3.00, d = 0.20), medium 314 effects (SD = 0.50, d = 0.50), and large effects (SD = 0.10, d = 0.80) using Cohen (1992)'s 315

traditional guidelines for *d* interpretation. The smallest effect size was set such that Likert style data could still be retained with the smallest possible effect size. Sample size was manipulated at 10, 30, 100, 500, and 1,000 data points. All combinations of the five sample sizes and four effect sizes were created, and each dataset was simulated 1,000 times, totaling 20,000 datasets.

The advantage of using mvtnorm and set SDs for each group was the ability to
approximate the assumptions of normality by randomly generating from a multivariate
normal distribution, and homogeneity by setting equal SDs for each group. In a repeated
measures design, the assumption of sphericity was met by setting the correlations between
levels in mvtnorm to zero. By maintaining the lowest level of relationship between levels, we
additionally controlled for power and examined situations of significance given the lowest
power scenario. During the data simulation, the standard deviation of the difference scores
was examined to maintain differences greater than zero, especially for low N simulations.

329 Analyses Performed

Descriptive Statistics. Means, mean differences between levels, and the confidence intervals for each mean can be found in the complete dataset online, https://osf.io/u9hf4/. For each simulation, we also calculated d values using the standard deviation of the difference score as the denominator (d_z , Lakens, 2013). The MOTE library was used to calculate the non-central confidence interval for each d value as well (Buchanan, Valentine, & Scofield, 2017; Cumming, 2014). This data was mainly used to determine if simulations were meeting expected values overall.

Parametric NHST - Repeated Measures ANOVA. Repeated measures

ANOVA using the ezANOVA() function in the ez library was utilized with type three sum of

squares (Lawrence, 2017). This style of ANOVA is used to compare the same individuals

across multiple or all conditions in an experiment. The null hypothesis states that there are

no significant differences between population means, and the research hypothesis posts that

there are differences between population means, but does not specify which population means may differ, just that one or more will differ as the alternative. This test uses the Fdistribution focusing on p values.

To determine where differences may exist, post hoc dependent t-tests are normally 345 analyzed in the event of a significant F-ratio. We did not run all pairwise comparisons, 346 instead focusing on the linear trend simulated by comparing level one to two and level two to 347 three. This set of comparisons also controlled the effect size between comparisons, as 348 comparing level one to three would have doubled the effect size. However, we assumed that 349 the typical researchers might compare all three pairwise combinations in practice and used a 350 Bonferroni correction across all three possible pairwise combinations to calculate p values for 351 post hoc tests. Therefore, while we only discuss the two comparisons, we utilized the more 352 stringent cutoff of the Bonferroni correction as we believe this procedure would be how the 353 majority of researchers would handle the data. Interested readers can find all three 354 comparison values in the complete dataset online. A p-value of less than .05 was binned as 355 significant, whereas p-values ranging from .10 to .05 were binned as marginally significant. Any p-values larger than .10 were binned as non-significant. A second set of p-value 357 comparisons was calculated given Benjamin et al. (2018)'s suggestion to change α criterion to less than .005. Any p-value less than .005 was binned as significant, while data ranging 359 from .005 to .10 was marginal or suggestive, and p > .10 was non-significant. 360

Bayesian Analysis: Bayes Factor. We compared a null model with one grand
mean for all three levels to an effects model wherein means were allowed to differ using the
BayesFactor package (Morey & Rouder, 2015). The default in this package is a Jeffreys prior
with a fixed rscale (0.5) and random rscale (1.0). BF were calculated, and follow up t-test
BFs were computed for the same two comparisons as in the previous models using default
priors from the BayesFactor package (e.g., Jeffreys prior for population variance, Cauchy
prior for standardized effect size). To compare Bayesian results to other statistical methods,
we used recommendations from Kass and Raftery (1995) to bin results into weak evidence

 369 (BFs < 3), positive evidence (e.g., akin to marginal p-values, BFs = 3-20), and strong 370 evidence (BFs > 20). BF interpretation should focus on understanding the odds of model 371 ratios, and these bins are used here as a convenient comparison to procedures that do have 372 set criteria for interpretation (Morey, 2015).

OOM: Ordinal Pattern Analysis. An R script of the Ordinal Pattern Analysis 373 from Grice et al. (2015)'s OOM program was provided from Sauer and Luebke (2016). We set the expected ranked pattern as level one less than level two less than level three. Once this pattern was defined, we then analyzed the data to see if each individual's set of 376 observations matched this expected ordinal pattern. PCC values were generated, and 377 c-values were computed by randomizing the data 1,000 times. Solely for purposes of 378 comparison, we used the following significance coding schema: significant studies had a high 379 PCC value (.50 < PCC < 1.00) and a low c-value (c < .05), marginal studies had a high 380 PCC value and a moderate c-value (.05 < c < .10), and non-significant studies had low PCC 381 values (PCC < .50), regardless of their c-values. 382

383 Results

Percent of Estimates

For all simulations, we first binned the estimates into significant, marginal, and 385 non-significant effect categories as described in the Analyses Performed section above. Next, 386 we calculated the percentage of these analyses that would be classified into each of these 387 categories, separated about by statistical analysis, sample size, and effect size. These 388 estimates were binned across both the overall and follow up post hoc tests, and the combined data is presented for this analysis. Since all three categories of binning total to 100%, we present only the significant and non-significant results. All analyses and findings can be 391 found online at https://osf.io/u9hf4/. Significant critical omnibus estimates are presented in 392 Figure 1. All figures discussed in this manuscript may be viewed as interactive graphics on 393 our OSF page through a provided Shiny app. In Figures with sample size on the axes, we log 394

transformed N to allow for visual distinction between sample sizes, as smaller N values were compressed when using the N=10 to 1000 on the axis. Both N and $\log(N)$ can be found in the Shiny app, along with the ability to zoom in to specific ranges of sample size.

For negligible effects at p < .05 (solid lines), we found that NSHT analyses showed a 398 predictable Type I error bias, in that they detected significant estimates with extremely 399 small d values as sample size increased. Binned BF values showed a similar pattern, but 400 were more conservative with less percent significant estimates. OOM analyses were the most 401 conservative, essentially never detecting an estimate in the negligible effect simulations. 402 Small effect sizes showed the same pattern for NHST, BF, and OOM results, with the 403 proportion of significant estimates increasing more rapidly and asymptoting at a smaller 404 sample size than negligible effects. At medium effect sizes, NHST analyses nearly always 405 detected significant estimates, while BF and OOM analyses would have been considered 406 significant around 75% of the time. Interestingly, with large effect sizes, OOM analyses 407 mirrored NHST by always detecting estimates, and BF analyses were generally more 408 conservative except at the largest sample size. Figure 1's dashed lines indicate the results if 409 values were binned at p < .005, and the differences between these results were very subtle. 410 Lowering α reduced the number of significant estimates at small N values for all four effect sizes, with more pronounced differences at negligible and small effect sizes. However, the 412 graphs converged to the same conclusion that large enough sample sizes could produce 413 significant results at negligible and small effect sizes. 414

Figure 2 portrays the results for non-significant binned simulations, which were the same for both α criterion. Across all effect sizes, BF and NHST showed similar results, where non-significant estimates were detected at lower sample sizes for negligible and small effect size simulations. At medium and large effect sizes, almost all estimates would have been considered significant, therefore, detection rates for non-significant estimates were around zero. OOM displayed a conservative set of findings, showing nearly 100% non-significant estimates at negligible and small effect sizes (mirroring results from Figure 1).

At medium effect sizes, approximately a quarter of estimates were non-significant, illustrating the conservative nature of OOM interpretations.

Percent Agreement

A goal of this project was to expand the toolbox of options for researchers to determine 425 what evidence supports their hypotheses by examining multiple methodologies. We 426 calculated the percent of time that all analyses agreed across overall and post hoc comparison 427 estimates. Figure 3 illustrates the pattern of 100% agreement on effects for critical omnibus 428 tests only at each sample size and effect size. Figure 4 portrays the results for post hoc tests, which only uses NHST and Bayes Factor analyses, as OOM does not have a post hoc test (i.e., the test is a pattern analysis that presupposes the expected direction of post hoc tests). When effect sizes were negligible and for small effects, agreement was best across small 432 samples and decreased across sample size, as NHST was overly biased to report significant 433 estimates and OOM and BF were less likely to do so. For medium and large effect sizes, 434 50-75% agreement was found, usually regardless of sample size. Additionally, we found that 435 for negligible, small, and medium effects, agreement for post hoc tests was higher than 436 agreement for overall comparisons. The post hoc comparisons for levels 1 to 2 and levels 2 to 437 3 were less likely to be binned as significant across negligible and small effects, so the 438 agreement levels were higher for these individual comparisons due to non-significant follow 439 up tests. The critical omnibus test was more likely to be significant due to the inclusion of effect of comparisons between level 1 and 3, which were double the effect size. However, these post hoc comparisons do not include the conservative significant binning from OOM, which decreased critical omnibus 100% agreement seen in Figure 3. Again, the differences between p < .05 and p < .005 were minimal. Complete tables of percentages of binning across critical omnibus and post hoc tests, along with agreement percentages broken down by 445 bins can be found at https://osf.io/u9hf4/.

447 Criterion Comparison

As the relationship between BF and p-values is already well documented, we will not 448 discuss them here beyond stating that we found the expected pattern shown in previous work (Rouder et al., 2012), and that individuals who wish to view this comparison, as well as all the other comparisons discussed here should visit our interactive Shiny application at our 451 OSF page. Of interest was the comparison of OOM indices to traditional NHST and 452 Bayesian indices. First, in Figure 5, PCC values are plotted against log BF values and 453 p-values. The log of BF was taken to include all values on a viewable axis, and all infinity 454 values were windsorized to the next highest point. Increasing sample size is shown by 455 increasing point size and lighter colors. Additionally, since OOM values are a combination of 456 PCC and c-values, c-values below .05 are shown as Xs instead of dots. Therefore, all values 457 PCC >= .50 that are also denoted as Xs would be considered significant in this example. 458 The provided Shiny application uses color to distinguish sample size differences, as well as 450 includes options to create each combination effect size and criterion individually. Only two 460 graphs are provided here to save space. 461 In Figure 5, the left hand column portrays the relationship between log BF values and 462 PCC values in negligible and medium effect sizes. With negligible effect sizes, we found large 463 variability in PCC values across a small span of BF values while sample sizes remained low, 464 but as N increased, we saw that the range of PCC values narrowed considerably with 465 increasing BF values. Therefore, as sample size increased, the PCC values constricted, while 466 BF values expanded. A similar pattern appeared when viewing the medium sample size 467 graph, as again PCC values became less variable with increased sample size, and BF tended 468 to increase both in variability and in value as the sample size grew. Here, we can see a 469 benefit of PCC, along with c-values, as increasing sample size portrayed more precision in 470 PCC, instead of the increased variability found in BF. 471 It is also important to note that within the negligible effects graph, while many of 472 these PCC values reached high values, that these values did not denote patterns that would

necessarily be seen as unique. c-values were a secondary measure of evaluation that
eliminated a number of these matches from being considered meaningful. A large majority of
points with larger sample sizes on the figure included low chance values, however, the PCC
values for these simulations were lower than a meaningful percent used for cutoff criterion.
This two-step process helped to weed out effects that were negligible, especially at larger
sample sizes.

Additionally, we compared p-values and PCC values, which are illustrated on the right 480 hand side of Figure 5. Again, PCC values showed far more variability with small sample 481 sizes, and the p-values associated with these smaller sample sizes were also quite variable. 482 Importantly, even when an effect was negligible, PCC values become less variable with 483 increasing sample size. PCC values also indicated that there was little evidence of the 484 hypothesized pattern by shifting toward zero. p-values decreased in variability at high 485 sample sizes and shifted toward minuscule values, thus, pointing toward rejecting the null 486 hypothesis. With medium effect sizes, both p-values and PCC values were variable at small 487 sample sizes. At larger sample sizes, p-values decreased towards floor effects (i.e. closer to 488 zero), while PCC values simply narrowed in range shifting slight above .50. The benefit of 480 multiple criterion evaluation here was clear, as p-values indicated significance as sample size 490 increased, while PCC values presented a more stable picture of effect sizes. While multiple 491 criterion may not completely reduce the interpretation of false positives in the literature, the 492 relationship between these values illustrated that multiple indices can provided a clearer picture of the evidentiary value available in a study.

495 Limitations

Within any study a number of limitations exist. The largest limitation of our study is
that we chose to focus on a simple three level repeated measures ANOVA design. The
benefit to this focus is the simplicity of understanding the relationship between analyses,
while also using a well understood NHST procedure. However, is possible that these same

relationships may or may not exist in alternative design contexts. Additionally, our choices 500 for classification of significant effects for p-values, BF, PCC, and c-values was based on what 501 we believe a reasonable researcher may designate; however, these classifications may vary in 502 the real world. We provide open access to our simulations and code so that an interested 503 party can tinker with these choices. We believe the global conclusions would likely be similar 504 across changes, however, the specific percentages and patterns would likely differ. Finally, 505 due to the specification of our simulation we did not violate any statistical assumptions. It is 506 possible that the violation of these assumptions may cause changes in the relationships we 507 see here. 508

509 Discussion

This manuscript was designed to showcase available methodologies to researchers and 510 to compare the conclusions each methodology might make in a given data environment. We 511 believe that the application of multiple methodologies might assist in strengthening our 512 conclusions and improving reproducibility by giving researchers the ability to weight various forms of evidence. We found that changing the threshold at which p-values are deemed significant had little to no effect on conclusions, especially at large sample sizes, regardless of 515 effect size. This finding is notable as the article by Benjamin et al. (2018) states that an 516 increase in sample size is likely to decrease false positives "by factors greater than two" 517 (p. 10), and work by Pericchi and Pereira (2016) state that an adaptive level of significance 518 would be beneficial in these circumstances, neither of which are not supported by our 519 simulations. Our science will not grow by moving the significance line in the sand, as this line 520 has already been shown to have "no ontological basis" (Rosnow & Rosenthal, 1989, p. 1277). 521 Instead, we need to embrace the multitude of perspectives available to us and to begin 522 to use a combination of approaches to qualify the strength of evidence. By comparing 523 multiple methodologies, we can see a more nuanced version of our data. Additionally, while 524 all of these methods have limitations, when taken together these methods can begin to 525

overcome these limitations. For instance, given a large sample size, we would expect that BF 526 values to be very large and p-values to be very small, both indicating that an effect exists. 527 However, if we also have a PCC value of .40, we may decide that it is possible that this effect 528 is very small and possibly negligible. This multifaceted approach may help to curb our 529 enthusiasm over small or negligible effects that may possibly not replicate. Regardless if 530 analyses agree or disagree on the presence of an effect, a researcher can investigate the size of 531 the effect and discuss conclusions accordingly. Each methodology behaves slightly differently 532 in given data environments, which might begin to highlight meaningful differences when 533 discussed together. 534

Some may contest that all of these analyses are capable of being hacked, like p-values, 535 through researcher degrees of freedom, choice of priors, or pattern choice, among other 536 actions (Simmons et al., 2011). Transparency throughout the research process is key to 537 eliminating these issues, as α changes may only encourage bad research practices with the 538 current incentive structure on publishing. Although we have the capability to share research 539 across the world, research often still occurs behind closed doors. The Open Science 540 Framework grants insight into research processes, allowing researchers to share their 541 methodologies, code, design, and other important components of their projects. In addition to posting materials for projects, pre-registration of hypotheses and methodology will be an important facet in scientific accountability. Further, with increased transparency editors and other researchers can weigh the evidence presented according to their own beliefs.

Our key suggestion in this project is the redefinition of evidentiary value. The current focus on p-values has shown to be problematic, as many of the studies from the Open Science Collaboration (2015) do not replicate at p < .05 or p < .005 (Lakens et al., accepted). With the change in transparency mentioned above, publishing research with solid research designs and statistics, regardless of p-values, will allow for a broader range of evidence to become available. Publishing null findings is critical in replication and extension for discovering the limits and settings necessary for phenomena. Registered replications and

reports will allow studies to be accepted prior to results being known, thus allowing 553 researchers to focus on experimental design and hypotheses appriori instead of p-values post 554 hoc. Reports should describe multiple indicators of evidence, such as effect sizes, confidence 555 intervals, power analyses, Bayes Factors, and other descriptive statistics (Finkel, Eastwick, & 556 Reis, 2015; B. A. Nosek & Lakens, 2014; van't Veer & Giner-Sorolla, 2016). 557 A misunderstanding of statistical power still plagues psychological sciences (Bakker, 558 Hartgerink, Wicherts, & van der Maas, 2016), and the effect of sample size, especially small 559 ones, was shown here by comparing the criterion available in these analyses. Often, 560 individual research labs may not have the means to adequately power a proposed study. 561 Multilab studies and collaboration with other scientists is fundamental to alleviating these 562 issues, while encouraging interdisciplinary science. Collaboration increases our statistical 563 abilities, as every researcher cannot be expected to be proficient in all methods and analyses, but teams of researchers can be assembled to cover a wider range of statistical skills to provide adequate estimates of evidence in their reports. We understand that there may be 566 resistance to the implementation of multiple methodologies as these new methodologies take 567 time and effort to learn. However, through the use of free programs (JASP, R, OOM, Shiny) 568 and tutorials (YouTube, Coursera, http://www.statstools.com), we believe all researchers are 569 capable of learning these analyses. We believe that through the expansion of our analytical 570 knowledge and application of these new methodologies, we can begin to attenuate some of 571 the strain currently placed on psychological science and to increase the strength of evidence 572

in our discipline.

 $\begin{tabular}{ll} Table 1 \\ OOM\ Ordinal\ Pattern\ Analysis\ Example \\ \end{tabular}$

1	2	3	4
Individual	Time 1	Time 2	Time 3
A	3	4	5
В	4	5	2

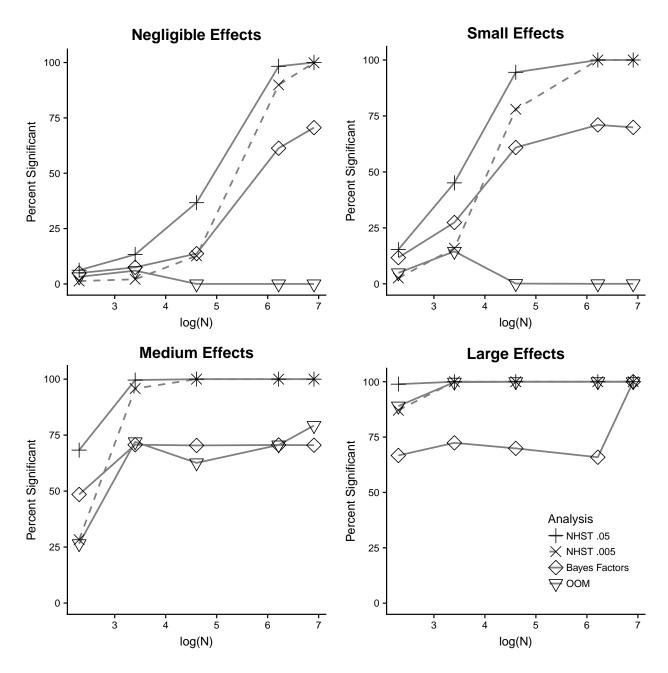

Figure 1. Percent of significant estimates at p < .05 (solid) and p < .005 (dashed) for each analysis given effect size and sample size.

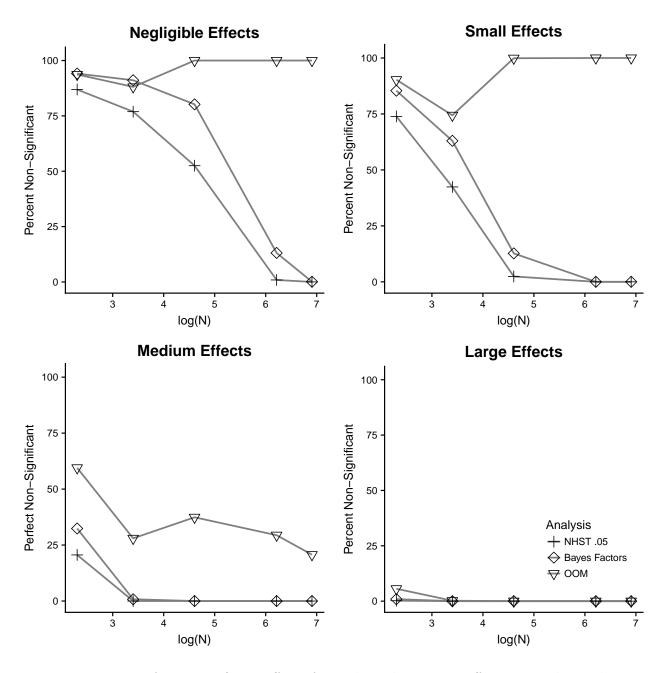

Figure 2. Percent of non-significant effects for each analysis given effect size and sample size.

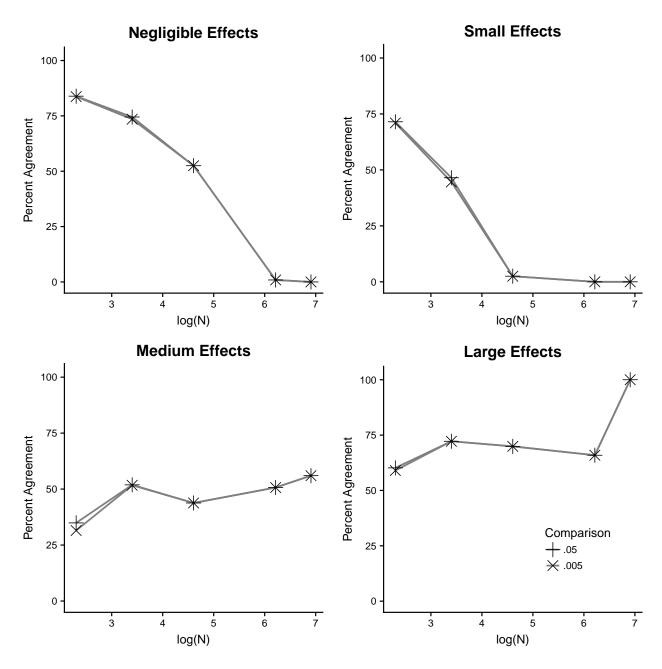

Figure 3. Percent of agreement across each analysis given effect size and sample size for omnnibus tests.

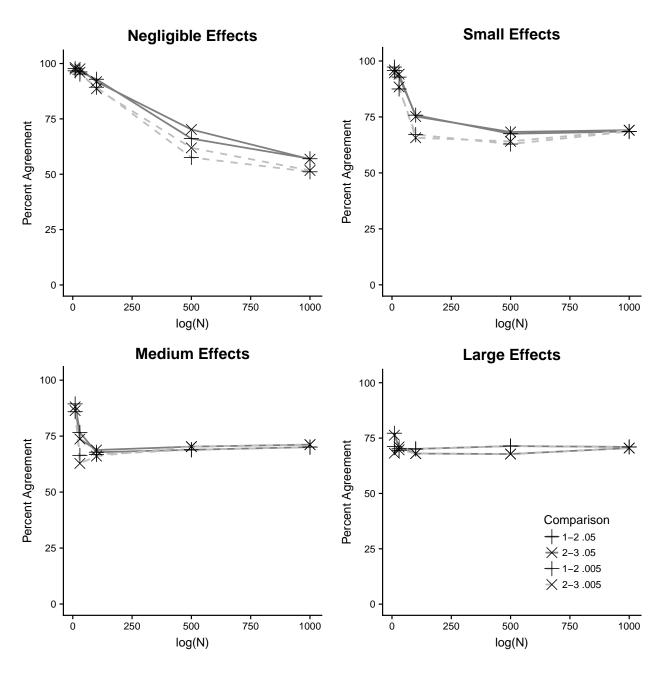

Figure 4. Percent of agreement across each analysis given effect size and sample size posthoc tests with p < .05 (solid) and p < .005 (dashed).

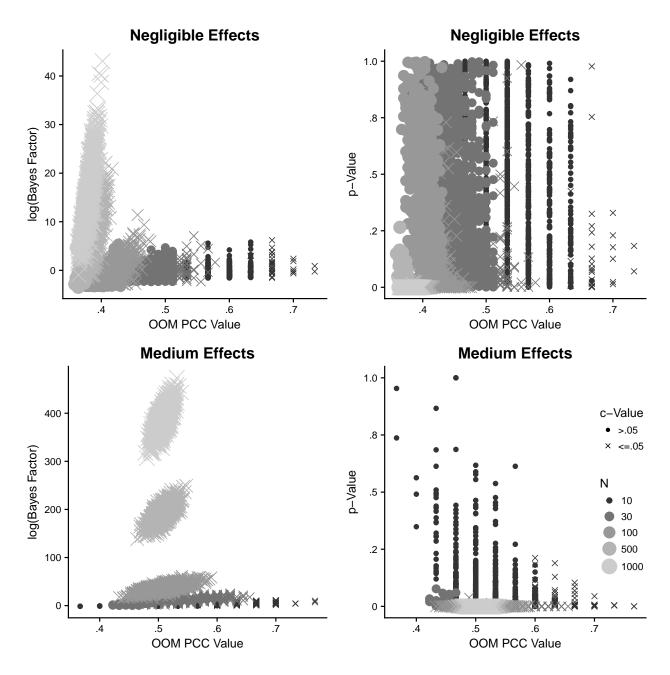

Figure 5. PCC and c-values plotted against p and BF values for negligible and medium effect size conditions. Xs indicate simulations with c-values < .05,which were binned as significant if they were found in conjunction with PCC values over .50. Point size and color indicates sample size wherein larger samples are lighter colors. Please note that the key for the entire set of graphics is in the bottom right hand corner.
