17 Abstract

Null hypothesis significance testing is frequently cited as a threat to the validity and 18 reproducibility of the social sciences. While many individuals suggest we should focus on 19 altering the p-value at which we deem an effect significant, we believe this suggestion is 20 short-sighted. Alternative procedures (i.e., Bayesian analyses and Observation Oriented 21 Modeling) can be more powerful and meaningful to our discipline. However, these 22 methodologies are less frequently utilized and are rarely discussed in combination with 23 NHST. Herein, we compare the possible interpretations of three analyses (ANOVA, Bayes 24 Factor, and an Ordinal Pattern Analysis) in various data environments using a simulation 25 study. The simulation generated 20000 unique datasets which varied sample size (Ns of 10, 30, 100, 500, 1000), and effect sizes (ds of 0.10, 0.20, 0.05, 0.80). Through this simulation, we find that changing the threshold at which p-values are considered significant has little to no effect on conclusions. Further, we find that evaluating multiple estimates as evidence of an effect can allow for a more robust and nuanced report of findings. These findings suggest the need to redefine evidentiary value and reporting practices. 31

Modeling, evidence

34

Beyond p-values: Utilizing Multiple Estimates to Evaluate Evidence

Recent events in psychological science have prompted concerns within the discipline 35 regarding research practices and ultimately the validity and reproducibility of published 36 reports (Etz & Vandekerckhove, 2016; Lindsay, 2015; Open Science Collaboration, 2015; van 37 Elk et al., 2015). One often discussed matter is over-reliance, abuse, and potential hacking of 38 p-values produced by frequentist null hypothesis significance testing (NHST), as well 39 misinterpretations of NHST results (Gigerenzer, 2004; Ioannidis, 2005; Simmons, Nelson, & Simonsohn, 2011). We agree with these concerns and believe that many before us have voiced sound, generally accepted opinions on potential remedies, such as an increased focus on effect sizes (Cumming, 2008; Lakens, 2013; Maxwell, Lau, & Howard, 2015; Nosek, Spies, & Motyl, 2012). However, other suggestions have been met with less enthusiasm, including a recent article by Benjamin et al. (2017) advocating that researchers should begin thinking only of p-values less than .005 as "statistically significant", thus changing α levels to control Type I error rates. Additionally, Pericchi and Pereira (2016) promote the use of fluctuating α levels as a function of sample size to assist with these errors. We argue it is not the p-value that needs to be rethought when seeking evidence, but rather what that p-value can tell you in relation to other indicators. While NHST and p-values may have merit, researchers have a wealth of other statistical tools available to them. We believe that 51 improvements may be made to the sciences as a whole when individuals become aware of the tools available to them and how these methods may be used in combination to strengthen 53 understanding and conclusions. Herein, we have chosen three methodologies to focus on: NHST, Bayes Factor comparisons, and Observation Oriented Modeling. We hope that by discussing these

comparisons, and Observation Oriented Modeling. We hope that by discussing these methodologies in terms of a simple statistical analysis researchers will be able to easily compare and contrast methodologies. For this discussion, it is important to understand their historical background, procedural steps, and limitations, which are outlined below. After this discussion, we describe a simulation study comparing methodologies and α criteria, and end

with a potential implications for researchers.

Null Hypothesis Significance Testing

Many attribute the frequentist NHST procedure to Ronald A. Fisher (Fisher, 1932).

However, Fisher's ideas are a far cry from the NHST procedure implemented today. Fisher

63 History

62

believed in creating one "null" hypothesis, which he described as a hypothesis to be "nullified", or shown incorrect, not as a zero-difference hypothesis (Lehmann, 2011). He also believed that the use of any omnibus level of significance showed a "lack of statistical thinking" (Gigerenzer, Krauss, & Vitouch, 2004). He instead believed we should report the exact significance value of a test and let others make their own decision about the claims, which is more in line with the current reporting recommendations provided by the American Psychological Association (American Psychological Association, 2010). Fisher spoke of this work to William Gosset, the man who created the Student's t-test and contributed work on 73 the correlation coefficient (Lehmann, 2011). Gosset in turn discussed the idea of an 74 alternative hypothesis, a piece not included in Fisher's procedure, with decision theorist 75 Egon Pearson. 76 From this discussion, Egon Pearson and Jerzy Neyman created Neyman-Pearson 77 decision theory. This theory consists of two hypotheses (i.e., null and alternative) and a 78 binary decision criteria (i.e., significant or not, Lehmann, 1993). However, this procedure created the possibility of researcher decision errors (Dienes, 2008). A researcher may falsely reject the null hypothesis (Type I error, α) or falsely fail to reject the null (Type II error, β). α levels set the binary decision criteria, which are used as the critical p-value for hypothesis testing (i.e., p < .05), and are thus seen as evidence to reject the null hypothesis. β and power are inherently linked, as the likelihood of finding a true effect increases when beta decreases (Maxwell & Delaney, 2004). Although α values can be chosen to be quite small, and methods can decrease β values as well, a researcher can never know if they have made

the correct decision, or a decision error. Thus, Neyman and Pearson clearly state that a hypothesis should not be blindly supported based solely on the estimates of one statistical 88 test, and that replication and reproduction of results are imperative. The recent work of the 89 Open Science Collaboration (2015) has also highlighted the need for replication studies and 90 interpretation of results in an appropriate context. Additionally, Neyman and Pearson 91 emphasized that use of set α s and β s is illogical and sought instead for researchers to adjust their analysis to the needs of the particular task at hand (Gigerenzer, 2004). 93

Current NHST Procedure

100

101

102

107

Neither Fisher's hypothesis testing, nor Neyman-Pearson decision theory quite match 95 the NSHT procedure as it is taught and applied today. Psychologists have largely adopted 96 an amalgamation of the two approaches. Here, we attempt to outline what we believe is the 97 most appropriate way to carry out the traditional NHST procedure, although we note that this is not necessarily how researchers carry out the procedure in practice:

- 1) Create two hypotheses, one to be "nullified" and one "alternative" hypothesis. Ideally these should be hypotheses that allow for a meaningful conclusion to be reached regardless of whether the null hypothesis is rejected or not.
- 2) Select an α level that is appropriate given the context of your research, your analysis 103 plan, and you research question, and do not blindly adopt an omnibus p-value. 104
- 3) Compute your given analysis. If your p-value is less than the chosen α , reject the null 105 hypothesis and state that there appear to be differences between your means; however, 106 if your p-value is greater than or equal to the value selected, do not reject the null hypothesis, and state that a difference between the means could not be supported. 108
- Given the mathematical constraints associated with the current NHST procedure as 109 delineated above, there are a number of assumptions that must be met before an analysis is 110 begun (Tabachnick & Fidell, 2012). Data need to have no missing values and no outlying or 111

influential observations. Data must have a normal sampling distribution, be linearly related, and have independent errors. Depending on the statistical test, data must also be checked for equal variances, sphericity, and additivity. These assumptions can be checked and, if necessary, corrected for; however, violations of these assumptions can lead to inaccurate decisions and attenuated power.

While this approach is widely used, there are many limitations associated with it. 117 First, this method can be sensitive to violations of the stated assumptions if the sample size 118 is not large enough to create a normal sampling distribution. These tests are not appropriate 119 for phenomena with non-normal sampling distributions, phenomena that are not linearly 120 related, or those that violate any of the other assumptions mentioned above (Tabachnick & Fidell, 2012). Even if assumptions are met, or nonparametric tests are implemented, this methodology does not allow a researcher to state anything about the absence of an effect 123 (i.e., no true differences). Through NHST, one can only discuss evidence regarding the 124 alternative hypothesis; one can never support the null hypothesis through this procedure. 125 Given the recent findings regarding reproducibility, showing support for the absence of an 126 effect is even more crucial (Bakker, van Dijk, & Wicherts, 2012; Lakens, 2017). 127

Bayes Factors

129 History

128

Thomas Bayes was a statistician and Presbyterian minister whose works are still influential today (Bellhouse, 2004). Bayes' theorem solved the inverse probability problem, namely that through the frequentist approach, one can only know the probability of data existing given a hypothesis being true, never the probability of a hypothesis being true given that the data exist (Dienes, 2008). Bayes' theorem allows one to calculate the probability of a hypothesis given some data (posterior belief) by using how probable one believes the hypothesis to be before data was collected (prior belief) and how probable one believes the data to be given one's hypothesis (likelihood). Thus, with his theorem, researchers are able

to update (through the use of the likelihood) our initial beliefs (our prior) given some data 138 (Gelman, 2004). Pierre-Simon Laplace pioneered Bayesianism and advocated for a broader 139 interpretation of this theorem (De Laplace, 1774). The use of Bayesian statistics has been 140 suggested as an NHST alternative (Dienes, 2014; Wagenmakers, 2007), but this approach has 141 largely been undervalued in favor of frequentist methods as, until recently, Bayesian analysis 142 required considerable computational effort. However, today we possess the technology 143 necessary to conduct Bayesian analyses efficiently. While open source software, such as R144 and JASP, require minimal learning to be able to effectively operated (Morey & Rouder, 145 2015), researchers will need to invest more effort to understanding the focus and 146 interpretation of Bayes Factor comparisons as they differ from traditional NHST.

The Bayesian framework can be viewed as a continuum, with objective Bayesian 148 analyses on one end, and subjective Bayesian analyses on the other (Press, 2002). While this 149 topic could lend itself to its own manuscript, here we will simply summarize the two 150 endpoints, and discuss where our analysis may be perceived to fall on the line. Objective 151 Bayesian analysis is closest to frequentist theory, as priors are set to be as uninformative as 152 possible to allow little, if any, influence on the estimates and distribution of the posterior; 153 thus, the data is allowed to maximally effect the posterior distribution. On the other end, 154 subjective Bayes analyses include rigorously informed priors so that current knowledge can 155 play a large role in the posterior. Our current analysis splits these two; we do not utilize 156 completely uniformed (objective) priors, as we can adjust for basic knowledge of the 157 constraints of our data type. Given the usual lack of information about underlying 158 distributions, a wider band of inclusion was used for prior information. The BayesFactor package (Morey & Rouder, 2015) assists greatly in the choice of prior and is especially user-friendly for applied researchers, as it makes use of recommended default priors that have 161 been chosen to be safe to assume under a broad range of data and topics (Rouder, Morey, 162 Speckman, & Province, 2012; Rouder, Speckman, Sun, Morey, & Iverson, 2009). Instead of 163 conventional F, t, and p-values, a ratio of the likelihood of the alternative model to the null 164

is report, usually BF_{10} . For instance, $BF_{10} = 20$ would indicate that the effects model is favored 20 to 1 over the null model. Conversely, if the BF_{10} were 0.10, the null model is favored 10 to 1 over the effects model.

168 Current Procedure

170

171

172

173

174

175

176

177

178

The procedure behind Bayes Factor (BF) comparisons requires two steps.

- 1) One must design two models for the data. For our purposes, the first of these models will be the null model, which states that there are no differences between means. The second model for these analyses is the effects model, which states that each mean is allowed to be different from the grand mean. In designing these models, one must choose the prior distributions that are believed to describe the data. Reasonable expectancies of where the data lie should be incorporated in this decision based on previous research into the studied phenomena (Rouder et al., 2012).
- 2) Analyze the data given the selected priors and models. Consider the BF and use the BF_{10} as evidence of how one should update their beliefs about the models.
- Based on the flexibility of the analysis, the only assumption that needs to be made is that data exists such that two competing, plausible models with different constraints may be specified. However, given the analysis method we have adopted, we additionally needed to ensure no missing data occurred in our dataset.
- Bayesian inference improves upon the traditional frequentist point of view by allowing not only a clear interpretation of the evidence provided by the data, but also the ability to speak in favor of the null hypothesis. It is important to note that while previous work has indicated that p-values and BF largely agree on which hypothesis should be supported, they differ in the strength of that conclusion, especially when p-values were slightly lower than α (i.e., .05 to .01; Wetzels et al., 2011). However, some limitations do arise in this paradigm. Bayesian analyses require the researcher to take an active role in the choice of prior

distributions for the phenomenon they are modeling, and this decision can take some effort 190 to fully understand; however, in the meantime there are packages such as BayesFactor that 191 allow the researcher simple default options that can readily lend themselves to many research 192 areas with little fear of being outrageous specifications. Further, unlike NHST, Bayesian 193 analyses do not necessarily control long-run error rates, as the focus is on updating current 194 model beliefs. Another concern that many researchers have is that these analyses are 195 necessarily sensitive to prior choice. However, research has shown that the choice of priors 196 has essentially no effect on conclusions when sufficient data has been collected as the priors 197 give way to the weight of the data (Klugkist & Hoijtink, 2007; Rouder et al., 2012) and when 198 reasonable priors are considered, data are only mildly sensitive to these (Haaf & Rouder, 190 2017). Finally, many believe Bayesian analysis to be too computationally intensive to 200 complete. However, many simple programs, packages, and tutorials exist to help ease the 201 transition from frequentist to Bayesian analysis (JASP Team, 2017; Kruschke, 2014; Morey & Rouder, 2015).

Observation Oriented Modeling

os History

204

James Grice argues that our problems as a science go beyond use of NHST and extend 206 into the philosophical ideas underpinning our research. Therefore, he developed a new 207 paradigm called Observation Oriented Modeling (OOM, James W. Grice, 2011, 2014; James 208 W. Grice, Barrett, Schlimgen, & Abramson, 2012). He reasons that by viewing psychology 209 through the lens of realism, instead of positivism, we should be able to properly and effectively conduct research and analyze data. In contrast to positivism (i.e., which is solely 211 concerned with finding an effect, not with how the effect occurred), realism is the belief that effects conform to their cause and that all theories have an underlying truth. By viewing 213 science as knowing nature through its causes, we can use Aristotle's four causes (material, 214 efficient, formal, and final) to think in terms of forming structures and processes for 215

phenomena. Switching to this philosophy allows for techniques that match the daily
activities of social scientists in their endeavors to unravel the story of how humans operate.
Using OOM, a researcher does not focus on population parameters and their various
underlying assumptions; instead, the researcher is encouraged to take a step back and to
focus on observations at the level of the individual.

Generally speaking, this approach can handle any type of data, including ordinal 221 rankings and frequency counts, as all analyses are calculated in the same general fashion (see 222 K. D. Valentine & Buchanan, 2013 for an example). This simplicity occurs because OOM 223 works on the deep structure of the data. Through observational definition, the program 224 separates these units into binary code. Deep structures can be arranged to form a matrix, 225 which can then be manipulated via matrix algebra, binary Procrustes rotation, and other 226 operations to investigate the data. The most important values from any OOM analysis are 227 the PCC (percent complete match) values. These values represent how well the observations 228 matched the stated or expected pattern or, in the case of causal modeling, how many of the 220 observations conformed to a given cause. Complete matches are the proportion of 230 observations that match the researcher-designated pattern on all dimensions. The PCC 231 value replaces all of the conventional values for effect size used in statistical analyses. The 232 analysis we focus on here (Ordinal Pattern Analysis; OPA) does not form any type of linear 233 or nonlinear equation or regression, but simply looks for those individuals who match the expected ordinal pattern (J. W. Grice, Craig, & Abramson, 2015). 235

In OOM, p-values are no longer utilized (James W. Grice, 2011). As a secondary form of reference value, a chance value or c-value, is obtained by randomizing observations a researcher set number of times, often thousands of times. This randomization procedure is akin to permutation tests, where the original data is shuffled a number of times to create a number of comparable data sets. These randomized data sets are then compared to the designated pattern. If the randomized data sets fit the pattern as well as or better than the actual data does, the c-value will be high (close to 1). Low c-values (close to 0) are

indicative of distinct observations that are not likely due to chance. Although low c-values, like low p-values, are desirable, c-values do not adhere to a strict cut-off and should be considered a secondary form of confirmation for the researcher that their results are distinct.

246 Current Procedure

247

248

249

250

251

252

253

254

255

259

260

261

The OPA is analogous to repeated measures ANOVA and contains two steps.

- 1) Designate the expected ranked pattern: each variable as being higher, lower, or equal to the other variables. See Figure 1 for an example of a defined pattern.
- 2) Analyze the data using the OPA. Consider the *PCC* and *c*-values in light of the data and use your best judgment as to whether or not the data conform to the expected pattern. This analysis only requires the assumption that the data exists such that a pattern may be designed.

As with all of these methodologies, limitations do exist. This approach is largely concerned with patterns of responses, not with magnitudes of differences, which may be an integral piece of information to some researchers. Unlike all approaches mentioned before, we do not discuss the probability of some data given our hypothesis here, and instead focus on the observed responses of the individual and how it may or may not behave as expected. Finally, similar to the Bayesian analysis, long-run error rates are not discussed in this methodology.

A Simulation Study

Simulated Data

In this study, we generated 20,000 datasets by manipulating sample size and effect size for a repeated measures design with three levels. These datasets were created using the mvtnorm package in R (Genz et al., 2017), and all code for simulations can be found at https://osf.io/u9hf4/. Likert data, ranging from 1 to 7, was created by rounding mvtnorm

estimates to whole numbers and truncating any data points out the appropriate range 267 (i.e. values < 1 were rounded to 1, and values > 7 were rounded to 7). The means for each 268 level were set to 2.5, 3.0, and 3.5, and effect sizes were manipulated by adjusting the 269 standard deviation to create negligible effects (SD = 3.39, d = 0.10), small effects (SD =270 3.00, d = 0.20), medium effects (SD = 0.50, d = 0.50), and large effects (SD = 0.10, d = 0.00) 271 0.80) using Cohen (1992)'s traditional guidelines for d interpretation. The smallest effect size 272 was set such that Likert style data could still be retained with the smallest possible effect 273 size. Sample size was manipulated at 10, 30, 100, 500, and 1,000 data points. All 274 combinations of the five sample sizes and four effect sizes were created and each dataset was 275 simulated 1,000 times, totaling 20,000 datasets. 276

The advantage of using mvtnorm and set SDs for each group was the ability to 277 approximate the assumptions of normality by randomly generating from a multivariate 278 normal distribution, and homogeneity by setting equal SDs for each group. In a repeated 279 measures design, the assumption of sphericity was met by setting the correlations between 280 levels in mutnorm to zero. By maintaining the lowest level of relationship between levels, we 281 additionally controlled for power and examined situations of significance given the lowest 282 power scenario. During the data simulation, the standard deviation of the difference scores 283 was examined to maintain differences greater than zero, especially for low n simulations. 284

285 Analyses Performed

Descriptive Statistics. Means, mean differences between levels, and the confidence intervals for each mean can be found in the complete dataset online, https://osf.io/u9hf4/. For each simulation, we also calculated d values using the standard deviation of the difference score as the denominator (d_z , Lakens, 2013). The MOTE library was used to calculate the non-central confidence interval for each d value as well (E. M. Buchanan, Valentine, & Scofield, 2017; Cumming, 2014). This data was mainly used to determine if simulations were meeting expected values overall.

Parametric NHST - Repeated Measures ANOVA. Repeated measures
ANOVA using the ezANOVA() function in the ez library was utilized with type three sum of
squares (Lawrence, 2017). This style of ANOVA is used to compare the same individuals
across multiple or all conditions in an experiment. The null hypothesis states that there are
no significant differences between groups, and the research hypothesis posts that there are
differences, but does not specify where using the F distribution focusing on p values.

To determine where differences may exist, post hoc dependent t-tests are normally 299 analyzed in the event of a significant F-ratio. We did not run all pairwise comparisons, 300 instead focusing on the linear trend simulated by comparing level one to two and level two to 301 three. This set of comparisons also controlled the effect size between comparisons, as 302 comparing level one to three would have doubled the effect size. However, we assumed that 303 researchers might compare all three pairwise combinations in practice and used a Bonferroni 304 correction across all three possible pairwise combinations to calculate p values for post hoc 305 tests. Interested readers can find all three comparison values in the complete dataset online. A p-value of less than .05 was binned as significant, whereas p-values ranging from .10 to .05 307 were binned as marginally significant. Any p-values larger than .10 were binned as 308 non-significant. A second set of p-value comparisons was calculated given Benjamin et al. (2017)'s suggestion to change α criterion to less than .005. Any p-value less than .005 was 310 binned as significant, while data ranging from .005 to .10 was marginal or suggestive, and p 311 > .10 was non-significant.

Bayesian Analysis: Bayes Factor. We compared a null model with one grand
mean for all three levels to an effects model wherein means were allowed to differ using the
BayesFactor package (Morey & Rouder, 2015). The default in this package is a Jeffreys prior
with a fixed rscale (0.5) and random rscale (1.0). BF were calculated, and follow up t-test
BFs were computed for the same two comparisons as in the previous models using default
priors from the BayesFactor package (e.g., Jeffreys prior for population variance, Cauchy
prior for standardized effect size). To compare Bayesian results to other statistical methods,

we used recommendations from Kass and Raftery (1995) to bin results into weak evidence (BFs < 3), positive evidence (e.g., akin to marginal p-values, BFs = 3-20), and strong evidence (BFs > 20). BF interpretation should focus on understanding the odds of model ratios, and these bins are used here as a convenient comparison to procedures that do have set criteria for interpretation (Morey, 2015).

OOM: Ordinal Pattern Analysis. An R script of the Ordinal Pattern Analysis 325 from J. W. Grice et al. (2015)'s OOM program was provided from Sauer and Luebke (2016). We set the expected ranked pattern as level one less than level two less than level three (see 327 Figure @ref:(fig:oom-pic). Once this pattern is defined, the we analyzed the data to see if 328 each individual's set of observations match this expected ordinal pattern. PCC values were 329 generated, and c-values were computed by randomizing the data 1,000 times. Solely for 330 purposes of comparison, we used the following significance coding schema: significant studies 331 had a high PCC value (.50 < PCC < 1.00) and a low c-value (c < .05), marginal studies 332 had a high PCC value and a moderate c-value (.05 < c < .10), and non-significant studies 333 had low PCC values (PCC < .50), regardless of their c-values. 334

Results

336 Percent of Estimates

For all simulations, we binned the estimates into significant, marginal, and non-significant effects and calculated the percent of each category of estimates by statistical analysis, sample size, and effect size. These estimates were binned across both the overall and follow up *post hoc* tests, and the combined data is presented for this analysis. Since all three categories of binning total to 100%, we present only the significant and non-significant results. All analyses and findings can be found online at https://osf.io/u9hf4/.

Significant omnibus estimates are presented in Figure 2. For negligible effects at p < .05 (solid lines), we found that NSHT analyses showed a predictable Type I error bias, in that they detect significant estimates with extremely small d values as sample size increases.

Binned BF values show a similar pattern, but are more conservative with less percent significant estimates. OOM analyses are the most conservative, essentially never detecting an 347 estimate in the no effect simulations. Small effect sizes show the same pattern for NHST, BF, 348 and OOM results, with the proportion of significant estimates increasing more rapidly and 349 asymptoting at a smaller sample size than negligible effects. At medium effect sizes, NHST 350 analyses nearly always detect estimates, while BF and OOM analyses will be considered 351 "significant" around 75% of the time. Interestingly, with large effect sizes, OOM analyses 352 mirror NHST by always detecting estimates, and BF analyses are generally more 353 conservative except at the largest sample size. Figure 2's dashed lines indicate the results if 354 values are binned at p < .005, and the differences between these results is very subtle. 355 Lowering α reduces the number of significant estimates at small n values for all four effect 356 sizes, with a more pronounced differences at no and small effect sizes. However, the graphs converge to the same conclusion that large enough sample sizes can produce significant results at negligible and small effect sizes. 359

Figure 3 portrays the results for non-significant binned simulations, which are the same for α criterion. Across all effect sizes, BF and NHST showed similar results, where non-significant estimates are detected at lower sample sizes for negligible and small effect size size simulations. At medium and large effect sizes, almost all estimates would have been considered significant, therefore, detection rates for non-significant estimates are around zero. OOM displayed a conservative set of findings, showing nearly 100% non-significant estimates at none and small effect sizes (mirroring results from Figure 2). At medium effect sizes, approximately a quarter of estimates were non-significant, illustrating the conservative nature of OOM interpretations.

59 Percent Agreement

A goal of this project was to expand the toolbox of options for researchers to determine
what evidence supports their hypotheses by examining multiple methodologies. We

calculated the percent of time that all analyses agreed across overall and post hoc comparison 372 estimates. Figure 4 illustrates the pattern of 100% agreement on effects for omnibus tests 373 only at each sample size, and effect size. Figure 5 portrays the results for post hoc tests, 374 which only uses NHST and Bayes Factor analyses, as OOM does not have a post hoc test 375 (i.e., the test is a pattern analysis that presupposes the expected direction of post hoc tests). 376 When effect size was negligible and for small effects, agreement was best across small 377 samples and decreases across sample size, as NHST was overly biased to report significant 378 estimates and OOM and BF were less likely to do so. For medium and large effect sizes, 379 50-75% agreement was found, usually regardless of sample size. Additionally, we found that 380 for negligible, small, and medium effects, agreement for post hoc tests was higher than 381 agreement for overall comparisons. The post hoc comparisons for levels 1 to 2 and levels 2 to 382 3 were less likely to be binned as significant across negligible and small effects, so the 383 agreement levels were higher for these individual comparisons due to non-significant follow 384 up tests. The omnibus test was more likely to be significant due to the inclusion of effect of 385 comparisons between level 1 and 3, which are double the effect size. However, these post hoc 386 comparisons do not include the conservative significant binning from OOM, which decreases 387 omnibus 100% agreement seen in Figure 4. Again, the differences between p < .05 and p <388 .005 are minimal. Complete tables of percentages of binning across omnibus and post hoc 389 tests, along with agreement percentages broken down by bins can be found at https://osf.io/u9hf4/. 391

392 Discussion

This manuscript was designed to showcase available methodologies to researchers and to compare the conclusions each methodology might make in a given data environment. We believe that the application of multiple methodologies might assist in strengthening our conclusions and improving reproducibility by giving researchers the ability to weight various forms of evidence. We found that changing the threshold at which p-values are deemed

"significant" had little to no effect on conclusions, especially at large sample sizes, regardless of effect size. This finding is notable as the article by Benjamin et al. (2017) states that an 399 increase in sample size is likely to decrease false positives "by factors greater than two" 400 (p. 10), and work by Pericchi and Pereira (2016) state that an adaptive level of significance 401 would be beneficial in these circumstances, neither of which are not supported by our 402 simulations. Our science will not grow by moving the significance line in the sand, as this 403 line has already been shown to have "no ontological basis" (Rosnow & Rosenthal, 1989, p. 404 1277). Instead, we need to embrace the multitude of perspectives available to us and to 405 begin to use a combination of approaches to qualify the strength of evidence. By comparing 406 multiple methodologies, we can see a more nuanced version of our data. Regardless if 407 analyses agree or disagree on the presence of an effect, a researcher can investigate the size of 408 the effect and discuss conclusions accordingly. Each methodology behaves slightly differently in given data environments, which might begin to highlight meaningful differences when 410 discussed together.

Some may contest that all of these analyses are capable of being hacked, like p-values, 412 through researcher degrees of freedom, choice of priors, or pattern choice, among other 413 actions (Simmons et al., 2011). Transparency throughout the research process is key to eliminating these issues, as α changes may only encourage bad research practices with the 415 current incentive structure on publishing. With the Internet, we can share research across 416 the globe, but research often still occurs behind closed doors. The Open Science Framework 417 grants insight into research processes, allowing researchers to share their methodologies, 418 code, design, and other important components of their projects. In addition to posting 419 materials for projects, pre-registration of hypotheses and methodology will be an important 420 facet in scientific accountability. Further, with increased transparency editors and other 421 researchers can weigh the evidence presented according to their own beliefs. 422

Our key suggestion in this project is the redefinition of evidentiary value. The current focus on p-values has shown to be problematic, as many of the studies from the Open

Science Collaboration (2015) do not replicate at p < .05 or p < .005 (Lakens et al., 2017). 425 With the change in transparency mentioned above, publishing research with solid research 426 designs and statistics, regardless of p-values, will allow for a broader range of evidence to 427 become available. Publishing null findings is critical in replication and extension for 428 discovering the limits and settings necessary for phenomena. Registered replications and 429 reports will allow studies to be accepted prior to results being known, thus allowing 430 researchers to focus on experimental design and hypotheses appriori instead of p-values post 431 hoc. Reports should describe multiple indicators of evidence, such as effect sizes, confidence 432 intervals, power analyses, Bayes Factors, and other descriptive statistics (Finkel, Eastwick, & 433 Reis, 2015; Nosek & Lakens, 2014; Van't Veer & Giner-Sorolla, 2016). 434 A misunderstanding of statistical power still plagues psychological sciences (Bakker, 435 Hartgerink, Wicherts, & van der Maas, 2016), and often, individual research labs may not have the means to adequately power a proposed study. Multilab studies and collaboration 437 with other scientists is fundamental to alleviating these issues, while encouraging interdisciplinary science. Collaboration increases our statistical abilities, as every researcher 439 cannot be expected to be proficient in all methods and analyses, but teams of researchers 440 can be assembled to cover a wider range of statistical skills to provide adequate estimates of evidence in their reports. We understand that there may be resistance to the implementation 442 of multiple methodologies as these new methodologies take time and effort to learn. However, 443 through the use of free programs (JASP, R, OOM, Shiny) and tutorials (YouTube, Coursera, 444 http://www.statstools.com), we believe all researchers are capable of learning these analyses. 445 We believe that through the expansion of our analytical knowledge and application of these 446 new methodologies, we can begin to attenuate some of the strain currently placed on 447 psychological science and to increase the strength of evidence in our discipline.
